Hemorrhage from the pregnant uterus almost always means separation of the placenta or of the embryo from its attachments, but malignant growths of the cervix, erosions, and polypi may have to be considered. Hemorrhage from a pregnant uterus is never due to malignant growths of the body of the organ, because pregnancy is practically impossible with such lesions. There are, however, two great difficulties in connection with pregnancy hemorrhages: these are to differentiate: (1) The uterine hemorrhage which occurs along with *extra-uterine gestation* from that due to *threatened abortion*: and (2) The bleeding of *placenta previa* from that due to the *separation of a normally situated placenta*.

In the first case, arising very early in pregnancy, the external hemorrhage occurs when the extra-uterine gestation is separated from its tubal or other attachments and is converted into a tubal mole, when it becomes extruded from the fimbriated extremity of the tube, or when the tube ruptures. Therefore, there may be a history of acute abdominal pain, faintness, and possibly collapse from internal hemorrhage. Along with this, the uterus will not be found obviously enlarged, whilst there is some sort of swelling in one or the other posterior quarter of the pelvis. Hemorrhage due to threatened abortion cannot be diagnosed unless the presence of an intra-uterine pregnancy can be established. Therefore, in this case we must look for the definite signs of a normal pregnancy, which in the early months will be: amenorrhœa, morning sickness, breast changes, enlargement of the uterus, Hegar's sign, and Braun's sign. Hegar's sign consists in the extreme softening of the upper part of the cervix and lower part of the uterine body, combined with the as yet unsoftened vaginal portion and globular tense fundus: it is found from the sixth to the eighth week. Braun's sign consists in the irregular shape of the uterus from the eighth to the twelfth week: one side is larger than the other, and an ill-defined groove is found between them. The diagnosis of inevitable abortion depends

upon finding some part of the uterine contents presenting through the dilating cervix. Incomplete abortion is difficult to diagnose, unless some definite products of conception have already been passed and recognized as such.

In the second case, occurring generally after the sixth month of pregnancy, it is of the greatest importance to be able to diagnose *placenta prævia*. The only definite sign is the feeling of the placenta through the cervix when it will admit of this method of investigation. The suggestive signs are those due to the filling up of the lower uterine segment by the placenta. The presenting part remains high up and movable, not engaged in the brim, and there is a sensation of great increase of thickness between the vaginal fornices and the presenting part. In any case of severe hæmorrhage, however, the cervix must be dilated so as to admit a finger, as treatment depends upon diagnosis, and no patient with a placenta prævia is safe until she is delivered and bleeding has ceased.

MICROPSIA. (See VISION, DEFECTS OF, p. 920.)

T. G. Stevens.

MICROSOMIA. (See DWARFISM, p. 232.)

MICTURITION, ABNORMALITIES OF.—A person in health micturates about five times during the twenty-four hours, the total amount of urine passed being about 1500 c.c., or 50 ounces. This varies according to the amount of fluid taken, the amount lost by perspiration, and so forth. The act of micturition is controlled by a nervous mechanism, a stimulus from the vesical mucous membrane starting an impulse which causes contraction of the detrusor muscle, and at the same time relaxation of the sphincter at the urethral orifice. The special centres controlling the motor functions of the bladder are in the spinal cord at the level of the third sacral nerve, whilst the brain controls these centres in response to sensory impulses received. The abnormalities of micturition which are met with in practice depend partly upon lesions of some portion of the urinary apparatus, and partly upon some change in the nervous mechanism controlling the act, and will be discussed from these points of view, and under ENURESIS (p. 270).

Increased Frequency of Micturition. A large number of diseases of the genito-urinary tract are accompanied by increased frequency of micturition, but the symptom may depend merely upon the fact that there is an increased amount of urine to be passed. Thus in *diabetes mellitus*, *diabetes insipidus*, and *chronic interstitial nephritis*, the increased amount of urine will cause an increased frequency of desire to micturate, provided the capacity of the bladder is unaltered. If the total amount of urine remains normal increased frequency of micturition may be due to some lesion of the genito-urinary apparatus, and consideration of the other symptoms of a case will often point to a definite diagnosis. Increased frequency does not necessarily imply that the bladder is the seat of the disease, as the symptom is present with any form of renal pyelitis, commonly calculous or tuberculous, or with prostatic enlargement.

It is important to ascertain the relationship between micturition during the day and the night. Normally, a healthy person should not wake during the night to pass urine, unless an excess of fluid has been taken; but if any inflammatory condition is present in the bladder, micturition will be present during the night, as well as increased frequency during the day. Any form of *cystitis*, or acute inflammatory conditions of the *prostate* or neighbouring organs, will cause increased frequency both day and night.

With *vesical calculus* there is increased frequency during the day, but often no urination is necessary during the night. The frequency during the day is increased with activity or exercise, or by the jolting movements of travelling, but is absent during a period of rest. If the presence of a calculus has excited cystitis, increased frequency of micturition will be present both day and night.

With *prostatic enlargement*, whether simple or carcinomatous, the increased frequency is most marked at night, and is commonly the first symptom of the disease noticed by the patient, generally a man of about sixty. The bladder is not emptied completely, so that the addition of a relatively small amount of urine from the kidneys soon fills up the incompletely emptied viscus and sets up afresh the desire to micturate.

In *vesical carcinoma*, increased frequency of micturition is present during both the day and night, as the infiltration of the vesical wall prevents the bladder from being distended without pain, and it is frequently associated with cystitis.

In *renal colic* caused by *calculus* or *blood-clot*, or torsion of a *movable kidney*, there may be increased desire to micturate, and the symptom may be present in inflammatory diseases in the pelvis, such as *salpingitis*, *pyosalpinx*, or a low-placed *appendicitis*, or in the secondary infiltration of the bladder by *carcinoma* of the *uterus* or *rectum*.

In *renal tuberculosis* increased frequency of micturition is often present before any infection of the bladder or change in the ureteric orifice can be detected by the cystoscope.

Increased frequency of micturition may be produced by mechanical obstruction to the normal vesical distention by a tumour occupying the pelvis, and is seen commonly with *ovarian cyst*, *uterine fibroid*, or a *retroverted gravid uterus*; these tumours will be found upon vaginal examination.

In children, increased frequency of micturition may be due to *phimosis*, *balanitis*, a *small urinary meatus*, *worms*, or *penile calculus* (p. 574). With urine of *high acidity*, with *oxaluria* (p. 523), with *phosphaturia*, and with *bacilluria* (p. 88), increased frequency may be present without other symptoms.

Changes in the Stream of Urine. An abnormality of the stream of urine may be due to a congenital deficiency of the terminal urethra, as in *hypospadias* or *epispadias*, or to some lesion mechanically obstructing the stream. Most commonly this is due to a *stricture* of the urethra. If the stricture is situated in the penile portion, the stream of urine is of small calibre but of fair force, whilst if the stricture is in the bulbous urethra the mechanical effect upon the stream of urine passing through the stricture into the urethra of wider calibre beyond the stricture is that the force is diminished, whilst the actual stream as it leaves the meatus is not thinned. A stricture at or near the urethral meatus forms a thin but forcible stream; but no reliance can be placed upon the complaint of a 'twisted stream'.

The obstruction to micturition by an *enlarged prostate* causes the stream of urine to be slow and forceless, so that it may fall vertically from the meatus instead of in the usual arched manner. This same dribbling of urine will be seen when a urethral stricture becomes much narrowed, or again when the bladder musculature has lost its contractile power, or in disease of the nervous system affecting the motor paths to the bladder.

In any case presenting an abnormality in the stream of urine careful inquiry should be made to ascertain if the stream has become gradually and progressively narrowed, as in stricture, or if the alteration in the force of the stream is accompanied by increased frequency of urination, as in prostatic hypertrophy in an elderly patient, or by urethral discharge in a case suggestive of acute prostatitis. A stricture may be diagnosed with certainty by careful endoscopic examination under air-distention, or, failing this, by the obstruction offered to the passage of a catheter or bougie. Prostatic enlargement or inflammation will be suggested by the history of the case, and confirmed by a digital examination of the gland per rectum; in the absence of a mechanical obstruction in the urethra examination should be conducted for disease of the spinal cord by testing the knee-jerk and other reflexes.

Sudden stoppage of the flow of urine during micturition may be caused by a small, movable *vesical calculus*, if the latter happens to engage in the internal urethral orifice or becomes impacted in the urethra. The same sudden cessation of the flow is caused occasionally by a tuft of a *vesical villous tumour* blocking the urethral opening during micturition. Usually the flow will be resumed after a few seconds unless the calculus has passed into the urethra, when it may be passed naturally or require to be removed by surgical means. If the symptom recurs, a cystoscopic examination of the bladder will distinguish readily between the two conditions.

The same sudden cessation of the stream may occur without any intravesical lesion as the result of *spasmodic contraction of the vesical sphincter*. Patients subject to this trouble (so-called *stammering bladder*) can at times pass urine quite normally, but at others the stream is interrupted frequently, or they may be unable to pass urine at all, especially in the presence of a second person.

Difficulty in Micturition. Frequently associated with some change in the character of the stream of urine, a patient may complain of difficulty in micturition, either as a hesitation in commencing the flow or a need to strain to maintain it. This, again, is most common with *urethral stricture* or *prostatic enlargement*, or may be due to impaction of a *calculus* in the urethra or to the formation of *blood-clot* in the bladder. A calculus may

be passed into the urethra and become arrested in the canal, but not so that it wholly obstructs the passage of urine. It is not uncommon for a calculus to occupy the dilated portion of the urethra behind a stricture, or occasionally a *prostatic calculus* projects from the gland into the lumen of the posterior urethra. A calculus so placed may increase in size by the further deposition of urinary salts whilst in the urethra, and cause difficulty in micturition: it may be felt in the canal from the outside, upon rectal examination, or upon passing a soft bougie into the urethra. Even if placed behind a stricture it may be felt by a fine guide or bougie passed to dilate the stricture. Difficulty in micturition may also arise from *prostatic inflammation* or from *tuberculous disease of the prostate*.

Difficulty in micturition due to the presence of *blood-clot in the bladder* will usually be indicated by the previous passage of blood-stained urine and by the constant efforts to micturate.

Difficulty in micturition in the female may be caused by a *pelvic tumour* by the drag or direct pressure on the urethra or vesical neck. This may occur with a *uterine fibroid* or a *pregnant retroverted uterus*. Occasionally, difficulty is produced by the direct infiltration of the urethra by a *carcinoma* of the vaginal wall or vulva.

Difficulty in micturition is not uncommon in *disease of the nervous system*, causing paralysis or paresis of the detrusor muscle of the bladder. This may be due to *trauma* and pressure on the spinal cord by blood-clot, or to *myelitis*, *tubercles*, *disseminated sclerosis*, *combined sclerosis of the cord*, *tumour of the spinal meninges or cord*, or *syringomyelia*. It must be remembered that it is not uncommon for the early cord-changes of tabes to affect the urinary organs, and that difficulty in passing urine may be complained of when the urethra and bladder are normal.

Atony of the bladder wall without any affection of the nervous mechanism, from recurring over-distention of the bladder, may cause difficulty in micturition.

Retention of Urine by which is implied the gradual accumulation of urine in the bladder, with inability to pass any per urethram may arise from *mechanical causes* obstructing the urethra, or from *derangement of the nervous system*. Retention of urine must be distinguished from *ANURIA* (p. 54), or failure of the kidneys to secrete urine, for in retention the kidneys are still functioning, and the urine is collecting in the distended bladder. Retention of urine occurring suddenly produces severe pain and strangury, but in cases of old-standing obstruction the bladder may be distended enormously before pain is severe. If the retention remains unrelieved urine may continually dribble away per urethram, when a condition resembling incontinence of urine is produced: this condition has to be distinguished from *true incontinence* of urine due to injury or paralysis of the vesical sphincter muscle. In true incontinence the bladder remains empty, urine flows away as soon as it passes down into the bladder, and there is no obstruction in the urethra: whereas, in the condition of involuntary passage of urine from an unrelieved distended bladder—*incontinence from overflow*, or *false incontinence*—the bladder may be felt distended in the suprapubic region, and there exists some nerve disease or some mechanical obstruction of the urethra or at the internal urethral orifice.

The common causes of retention of urine are *urethral stricture* and *prostatic enlargement*. In stricture, it does not necessarily follow that the urethra is occluded entirely by the fibrosis, but rather that some spasm or congestion is present at the stricture, from exposure to cold or indulgence in alcohol, when a small catheter may be passed. In elderly men with *prostatic hypertrophy*, acute retention may occur early in the disease from a congested condition of the enlarged gland, or in the later stages be due to actual obstruction of the urethra by a localized enlargement from either lateral lobe or the so-called middle or third lobe which acts as a ball-valve to the internal urethral orifice in such a manner that each forced attempt at urination closes the orifice more securely. A large coudué catheter can usually be passed readily: but in cases of acute retention, especially in those of old-standing obstruction in which the kidneys are probably affected by the backward pressure, *the urine must be drawn off very slowly*, otherwise fatal anuria may be induced.

A case of acute retention of urine from *stricture of the urethra* will generally be that of a comparatively young patient, who will give a history of former gonorrhoea, gradually increasing difficulty in micturition, narrowing of the stream, and inability to finish the flow completely without some dribbling of urine. Examination of the urethra by an

endoscope, or by the passage of olivary-pointed flexible bougies, will reveal the presence of a stricture.

In *prostatic enlargement* the patient is usually above the age of fifty-five years, has been troubled with increasing frequency in micturition, especially at night, with straining and loss of force in the stream of urine. Per rectum, the prostate may be found to be enlarged both from above downwards and laterally; it may be smooth, elastic, and movable in the pelvic space in the case of adenomatous enlargement, or nodular, hard, irregular, and fixed in the case of carcinoma; the subjective symptoms of both are very similar. In some cases the prostate may not appear to be much enlarged upon rectal examination, though it is causing an intravesical tumour which obstructs urination, or a firm fibrous collar around the internal urethral orifice which gives rise to marked prostatic symptoms. In prostatic cases, even a large catheter of coudé form can usually be passed into the bladder readily. Retention of urine may also be present in cases of *acute prostatitis* or of *prostatic abscess*.

Acute retention of urine may be produced by other causes than the above. A *small calculus* may be passed into the urethra and totally obstruct the passage of urine. This may occur at any age, and the calculus become arrested at some narrow portion of the canal—usually at the meatus or at the membranous urethra. The urethra may lodge a calculus for some time with comparatively little pain; but more often the stone passes into the canal during micturition, causing a sudden pain, with cessation of the flow of urine and dribbling of a few drops of blood. The calculus may be palpated if it lies in the penile urethra or in the perineum, or will be felt on passing a metal instrument into the urethra.

Retention may be caused by the blockage of the internal urethral orifice by the free portion of a *pedunculated vesical tumour*. On any attempt at micturition the growth is forced into the orifice and obstructs it. These cases are rare, but in one under the care of the writer, a man, owing to his inability to pass any urine, had been condemned to catheter life on the assumption that he had prostatic enlargement. No enlargement could be felt per rectum, but upon cystoscopic examination a papilloma was found in the bladder, attached by its pedicle just above the urethral orifice and obstructing the flow of urine.

Retention of urine may occur with *traumatic rupture of the urethra*, often associated with fracture of the pelvis.

Retention of urine may also occur with *paralysis* of the *motor nerves* of the detrusor muscle of the bladder, or interference with the spinal centres by compression paraplegia, tabes dorsalis, or myelitis, each being diagnosed on examination of the nervous system; or as a *reflex spasm of the vesical sphincter* after operations upon the rectum or neighbouring organs.

In other cases, retention of urine is present in association with other symptoms of *hysteria*; but care must be taken not to give a diagnosis of hysteria until all other causes of retention are excluded. These cases usually occur in children or in young women.

Retention of urine occurring after operations about the anal or rectal areas or for hernia, etc., will be diagnosed readily.

Pain during Micturition. Pain may be present *during* or *immediately after* micturition, and it is important to ascertain not only the period at which it is present, but also the actual *location* of the pain. If pain is present in the urethra during micturition it usually indicates that a stricture or some inflammatory process is present, the latter being evidenced by a urethral discharge (see DISCHARGE, URETHRAL, p. 227). If pain is experienced *immediately after* micturition, and felt as a tingling or pricking sensation in the glans penis, there is some inflammatory or irritant process at the trigonal region of the bladder. Formerly this symptom was looked upon as diagnostic of vesical calculus, and though it is almost a constant symptom of the latter, provided the calculus is not trapped in a post-prostatic pouch, it is also present in cystitis, tuberculous or otherwise, in vesical carcinoma which is infiltrating the bladder base, and in acute or subacute prostatic infections. Prostatic infection can be diagnosed by the history of the case, usually following an acute urethritis, and by a rectal examination. Tuberculous cystitis usually occurs in young adults, and frequently other tuberculous lesions are present in the genito-urinary organs, such as the epididymis, vas deferens, seminal vesicles, or prostate, whilst

the urine contains not only blood and pus, but tubercle bacilli. Cystitis from other causes, and vesical growth or calculus, can be ascertained upon cystoscopic examination.

Pain may be felt in the *perineum* during and after micturition in cases of prostatic disease, especially if much straining occurs during micturition, or may be felt in both the perineum and the anal area in vesical carcinoma.

In the female, pain is felt at the urethral orifice and in the vulva after micturition in cases of cystitis or vesical carcinoma.

It should be noted that in either sex severe pain may be present at the termination of the urethra after micturition when a *calculus* is impacted in the *vesical end of a ureter* (Fig. 447, p. 558), especially if the latter is partially prolapsed into the bladder. In one such case the patient would hold her urine for hours rather than pass it, owing to the pain that followed micturition.

Micturition through Fistulæ.—Urine may pass, either wholly or in part, through a fistulous track communicating with the urinary organs, such opening being the result of preceding disease or injury. Occasionally, owing to congenital malformation of the urethra or bladder, urine passes by an opening in the perineum, pubes, or into the vagina; but these cannot be regarded as fistulæ.

Urinary fistulæ in connection with the urethra are most common as the result of peri-urethral abscess, stricture, or some operation; and in a case in which a penile fistula is present it is necessary to ascertain if the calibre of the urethra is in any way narrowed by cicatricial inflammation. A fistula may open in the perineum as the result of inflammation and extravasation behind a stricture, following an operation upon the lower urinary organs, or in the female into the vagina from damage during parturition or some vaginal operation. In cases in which a fistula opens into the vaginal fornix, the urine may leak from the bladder or from the lower end of the ureter. The opening is usually small and embedded in an area of cicatricial tissue, so that it is very difficult to pass a probe along the track. In these cases, evidence of the nature of the fistula may be obtained by filling the bladder with some sterile coloured solution, such as weak methylene blue—if the opening is in communication with the bladder, coloured solution will appear in the vagina, but if the urine comes from the ureter, no stain will be found. Evidence may also be obtained by means of the cystoscope, when a cicatricial area may be found in the bladder surrounding a retracted fistulous opening, or the ureteric orifice of one side may be found displaced from its normal situation by the scar contraction when the ureter is at fault. In these cases of ureteric injury it may be impossible to pass a bougie into the ureter more than a very short distance, the tip being arrested by the scar tissue.

A urinary fistula may be present in the suprapubic area in connection with the bladder, or in the lumbar area communicating with the kidney, as the result of operations on these two organs. A fistula has been seen in the iliac fossa as the result of an operation on the ureter, or after the opening of an abscess formed around the ureter from the ulceration caused by a ureteric calculus.

Disorders of Micturition from Diseases of the Nervous System.—In most of the foregoing paragraphs symptoms referable to the urinary organs have been stated to be due to disease of the urinary organs; in some cases to disease of the nervous system, such as myelitis, tabes dorsalis, or hemiplegia; in spite of repetition it is advisable to gather these under one heading. The control of the act of micturition depends upon the integrity of the nervous system; for although special centres exist in the lower segments of the spinal area presiding over the motor functions of the bladder, the impulse calling for action of these centres is supplied by the brain after a stimulus has been conveyed to the latter by the sensory nerve-fibres from the bladder. There are two centres in the lower spinal segment, by one of which the detrusor muscle of the bladder is brought into action, and by the other the sphincter muscle surrounding the vesical outlet is maintained in tonic contraction until inhibited by the same stimulus which produces contraction of the detrusor. The two vesical muscles are thus antagonistic in their action, the detrusor contracting and the sphincter relaxing in answer to the stimulus to micturition. In the diagnosis of all neuroses of the bladder it is most important to exclude all lesions of the urinary apparatus, and not to overlook the fact that vesical symptoms are often produced by some lesion in the kidney when the bladder on careful examination appears quite normal.

a. Irritability of the Sensory Nerves of the Bladder. Some patients experience an urgent

and frequent desire to pass urine, often every half-hour, though no objective symptoms of disease can be found, and all inflammatory lesions can be excluded; there is no pain and no increased frequency of micturition during the night. The cases have received the name of *cystalgia*, *hyperaesthesia vesicae*, and *irritable bladder*, and they must be distinguished carefully from those in which there is some lesion of the urinary organs, the rectum, and of the female pelvic organs.

Workers in aluminium sometimes develop trouble amounting almost to incontinence of urine without necessarily showing evidence of gross changes in the nervous system.

b. Irritability of the Motor Nerves of the Bladder. In this condition there is a spasmodic contraction of the sphincter muscle of the bladder, with resulting retention of urine or great difficulty in micturition. There is no stricture or urethral obstruction, as shown by the ease with which a catheter is passed, nor is there any prostatic enlargement. The neurosis is not confined to the male sex, and is seen in hysteria as well as in those nervous affections which affect the spinal centres, such as myelitis, lateral sclerosis, and tabes dorsalis.

c. Paralysis of the Motor Nerves of the Bladder may affect the peripheral nerves or spinal elements, but the results as regards the bladder are the same. If the nerves supplying the detrusor muscle or its spinal centre be paralysed, retention of urine occurs, and the patient can expel urine only by the force of the abdominal wall. If the sphincter muscle is affected, it becomes relaxed, and urine dribbles away. In many cases only part of the motor tract is affected, so that the power of the bladder is not abolished but diminished, and a portion of the urine is retained in the bladder after micturition. The bladder may be affected thus in compression of the spinal cord by fracture, or hemorrhage into the membranes, in myelitis, paraplegia, and tabes.

d. Destruction of the Spinal Centres for Micturition, by injury, softening, or compression, gives rise to incontinence without distention of the bladder. The urine dribbles from the urethra as fast as it enters the bladder.

R. H. Jocelyn Scurr.

MOUTH, PIGMENTATION OF. (See PIGMENTATION IN THE MOUTH, p. 641.)

MUCUS IN THE STOOLS. This occurs in such a variety of conditions that it is impossible to give a complete differential diagnosis of them here. Its presence always indicates organic disease, usually of the large bowel, for if it comes from the small bowel it will, unless the motions are very fluid, be so incorporated with them that it cannot be seen. It occurs in *malignant disease of the colon* as a clear glairy mucus, often blood-stained, and it has the same characters in *intussusception*, for the obstruction in both these cases accounts for the absence of fecal colouring. It is often seen in *constipated motions*, the hard feces having led to irritation of the large bowel, with consequent excessive secretion of mucus: if this has lain some time in the bowel it has become coagulated into white

Fig. 386. Tubular mucus cast of the large intestine, much reduced in size, from a case of mucous-membranous colitis. The cast measured 25½ inches in length.

shreds, which can be seen attached to the motions and look like parasitic worms. In severe cases a motion may consist almost entirely of these shreds: there may be little fecal matter. If the mucus has not lain so long in the bowel, it appears like a jelly outside the motion. Sometimes, especially in adult women who are constipated, complete casts of the bowel formed of coagulated mucus are passed: they may be a foot or more in length (*Fig. 386*). Often, however, by the time they are passed, they have become broken into fragments which the patient describes as skins, and which look not unlike segments of tape-worm. Patients passing this variety of mucus are said to have *membranous colitis*.

In the more acute varieties of inflammation of the bowel the mucus passed is jelly-like and semi-fluid, of varying colour according to the amount of faecal staining. In severe cases of *enteritis* the motions consist of nothing but mucus and blood. It is impossible to attempt to differentiate here between all the numerous varieties of enteritis. *W. Hale White.*

MUCUS IN THE URINE is generally of little clinical significance. Many normal urines, particularly those of women, develop a faint or even a more definite deposit of mucus, which may remain in suspension or may accumulate as a light floccular deposit at the bottom of the specimen-glass. Such mucus is a normal product of the epithelial cells of the urinary passages. It may indicate catarrh of the mucous membranes; but such catarrh will be shown more decisively by the occurrence of epithelial cells or actual pus corpuscles, or by a cause for catarrh such as *OXALURIA* (p. 523); diagnosis depending not upon the mucus but upon the other substances present with it. It is important not to mistake elongated strands of mucus for tube-casts; the error is particularly apt to occur if the cover-glass, on being pressed down on a specimen stained with methylene blue, slips slightly and draws out the mucus into long narrow strands. When numbers of these are seen all parallel with one another they are not likely to be mistaken for casts. Mucus stains readily either with methylene blue or with eosin, but exhibits no structure beyond granular particles, or cells that may have become entangled in its meshes.

If a male patient has formerly suffered from gonorrhœa, a residual catarrh of the glands in the prostate often persists long after the cure may have seemed to be complete. Urine from such a case, looked at in a tall glass vessel, often exhibits numerous filaments or 'prostatic threads', consisting for the most part of mucus coming in the form of casts from the prostatic tubules. *Herbert French.*

MYOSIS. (See PUPIL ABNORMALITIES OF, p. 674.)

NAILS, AFFECTIONS OF THE.—Various pigmentary and degenerative changes may occur in the nails as the result of occupation, as in dyers, washerwomen, jewellers, confectioners, and others; or the condition known as *pterygium* may arise, the fold of skin at the proximal end of the nail adhering and growing over the nail, like a 'wing'. The nails are liable to attack also in such cutaneous affections as ringworm, favus, eczema, psoriasis, and epidermolysis bullosa. The differences between the onychomycosis due to *ringworm* and that due to *favus* are described in the article on FUNGUS AFFECTIONS OF THE SKIN (p. 309). In *eczema*, usually the first sign of involvement of the nails is pitting, which gives them an appearance somewhat resembling orange-rind. They become discoloured and thinned, transverse and longitudinal splitting follows, and finally exfoliation occurs. In long-standing cases they may be thickened to the extent of deformity. In *psoriasis*, if the matrix of the nails is attacked, they become furrowed transversely, and dull in colour; later the nails split and may be shed, but not permanently. In other cases, instead of the matrix being affected, the nails are discoloured about the free border, and they become thickened as the discoloration extends downwards to the root. In *epidermolysis bullosa* there may be repeated bleb-formation at the finger-ends, causing atrophy of the skin and loss of nails. The signs of nail involvement in these three conditions are sufficiently distinctive to obviate confusion between them; and the lesions elsewhere will aid the diagnosis.

Trophic changes in the nails may also be consequent on *acute illness* (Fig. 387) or *senile decay*, or they may occur without any apparent cause: the longitudinal striae may be exaggerated, transverse furrows may appear, or white spots may develop, and a large part or the whole of the nail may become white (*leuconychia*). With this condition *spoon-nails* may be associated; the nail becomes thin and hollowed, either from side to side or from above down. Shedding of the nails may occur not only in distinctively cutaneous affections, but also in diabetes mellitus and syphilis, in locomotor ataxy and other nervous disorders. Either without definite etiology, or in connection with inflammation of the finger-tips,

the nail may be separated from its bed without being actually shed. *Onychia*, or inflammation of the nail, is in some instances due to syphilitic or tuberculous infection; in the latter case associated scrofulous lesions will often be found in the eyelid and elsewhere. Onychia, however, may also be due to trauma, or to contact with irritants used in industries, or may be idiopathic. Whatever the cause, the condition cannot be mistaken. If the process is acute there is great pain, with redness; suppuration takes place beneath the nail, which becomes thickened and discoloured, and is ultimately shed, leaving an unhealthy sore. If this should fail to heal, the lymphatics may be involved, and the case becomes one of *paronychia*, or whitlow. This condition is sometimes caused by the pressure of tightly-fitting boots, or by irritation set up by the edge of a badly-cut nail—

Fig. 587. From a water colour sketch of the nails, showing a uniform white band and transverse ridge due to lobar pneumonia three months previously.

usually that of the big toe. *Onychorrhexis*, brittleness of nails, may be either congenital or acquired. It is sometimes present in cheiropompholyx, and in other cases is associated with nervous affections and anomalies of development. In *onychauris*, hypertrophy of the nail, there may be overgrowth in one or in all directions, accompanied by distortion or discoloration, and sometimes by inflammation. In some cases the free end may grow to a great length, and may become twisted like a ram's horn (*onychogryphosis*). This curious distortion is often found in connection with congenital ichthyosis. A rarer condition of modified nutrition is that known as *egg-shell nail*, which is intimately associated with hyperidrosis; it has been met with in debilitated young women; the nail tends to grow upwards rather than forwards; its connection with the distal portion of the bed is enfeebled; and in typical cases the colour is precisely that of the inner face of the shell of a hen's egg—a delicate combination of white and purple. It has been suggested that, owing to the maceration of the distal portion of the nail-bed due to hyperidrosis, there is

interference with the normal cornification of the nail-plate. Whatever the process, the diagnosis is clear. Transverse ridging of the nails due to previous illness (*Fig. 387*) is described on p. 933. (See also FINGER, SORE, p. 301.) *Ernest Dore.*

NANOSOMIA.—(See DWARFISM, p. 232.)

NAPKIN-REGION ERUPTIONS.—Infantile eruptions in this region, when they are a manifestation of *congenital syphilis*, are usually erythematous or papular, but they may also be pustular, bullous, squamous, or polymorphic; in all cases alike they are distributed symmetrically on the buttocks. Frequently, around the anus and the genital organs the papules are moist and coalescent, and form flattish condylomata. Similar lesions are also found on the soles, palms, forehead, and around the mouth, and in these regions also the distribution is symmetrical. The eruption is as a rule transitory. The other symptoms of hereditary syphilis are so characteristic that the lesions here described are seldom liable to misinterpretation. The skin eruption is usually preceded by a chronic coryza ('snuffles') and laryngitis. Often the nails are severely affected coincidently with the skin. The colour of the lesions, approximating to the characteristic raw-ham tint, the loose, dry, *café-au-lait* skin, the senile aspect of the face, and the accompanying cachexia, form a distinctive clinical picture.

A napkin-area eruption which was often mistaken for congenital syphilis is the *infantile erythema of Jacquet*. It is a process which manifests itself in: (1) Simple erythematous, (2) Erythemato-vesicular, (3) Papular, (4) Ulcerating forms. These may develop consecutively or coincidently. The most common are the erythematous and the papular. All alike are probably due in part to the irritation set up by moist or soiled napkins, but vasomotor irregularities and gastro-intestinal toxæmia may also be concerned in the etiology. The preference sites of all four forms of the eruption are the *convex* surfaces of the buttocks, of the thighs, and of the scrotum or vulva. In the simple erythemas, of which the usual subjects are quite young infants, the rash may be limited in mild cases to the genitalia, the inner sides of the thighs, and the perineum, while in severer cases it may extend to the lumbar region, the lower abdomen, and the calves and heels. In the erythemato-vesicular form there appear on the convex surfaces towards the centre of the erythematous areas small bright-red erosions which, forming groups of from two or three to a dozen or more, may become confluent: the erosions are preceded by vesicles, which may usually be found near the borders of the reddened area. The erythemato-papular form of the eruption is met with when the erosions just described have thrown up flattened granulations, which give to the lesions the appearance of flat, reddish papules. In this stage the heels and the lower abdomen may be involved in the erythema. In the fourth form of the eruption the erosions, failing to granulate, develop into ulcers, with sharply defined borders or coalescing into vernicular lesions. They are confined to the convex surfaces, the folds always escaping. Attention to the appearance and distribution of the lesions, and the course they run, together with the absence of the more familiar signs and symptoms of congenital syphilis, will prevent confusion with that disease, or with the condition styled vacciniform erythema of infants.

Pemphigus neonatorum consists of an eruption of bullæ on the thighs and buttocks in new-born infants. It is not, however, confined to this region, but attacks other parts, including the face, and this is true also of the bullous impetigo of older babies, which, like pemphigus neonatorum, is a form of the impetigo contagiosa of Tilbury Fox. The diagnosis of these affections has been given under BULLÆ, p. 123.

In the '*seborrhæic eczema*' or '*seborrhæic dermatitis of infancy*' the whole napkin region is occupied by a uniform bright-red rash, for the most part covered with moist or greasy yellowish scales, though in prominent parts the surface may be smooth and polished. The margins of the area are sharply defined. The rash often extends downwards to the thighs and calves, and upwards to the umbilicus, while beyond this area there are smaller patches and many pin-head, red, scaly papules. Other parts that are attacked frequently are the bends of the knees, the flexures of the elbows, the axillæ, the sides of the neck, the nasolabial folds, and behind the ears. On the scalp will generally be found a red, squamous or crusty eruption. The diagnosis rests upon the distribution and the sharply defined margins, with the patches and crusted papules. It is assisted by

the readiness with which the eruption yields to mild local parasitocidal applications. In cases of congenital syphilis which mimic this condition, the presence of the concomitant specific signs, enumerated above, will prevent confusion between that disease and 'seborrhoeic eczema'.

In adults the same region, known as the bathing-drawers area, is liable to attack in a number of affections. In *eczema marginatum* (preferably termed *tinca marginata*), *dhobie's itch*, and *erythrasma* the eruption occurs exclusively, or almost exclusively, in this region: of these affections the differential diagnosis has been given under 'Ringworm' (p. 309). In *pediculosis pubis* the pubes may alone be affected, or the parasite may wander to the abdomen, the thorax, the axilla, and may even reach the beard, whiskers, and eyelashes. The diagnosis of this condition is generally obvious. In *scabies* the lesions may be very slight on the hands and wrists, and the brunt of the attack may be borne by the penis and scrotum, the lower part of the abdomen, and the thighs. In *psoriasis* the eruption is sometimes very severe in the bathing-drawers area, of which the surface is an almost uniform deep red, and is the seat of profuse desquamation, while on the special sites of election—the knees and elbows—the lesions may be quite insignificant. In *eczema intertrigo* and *erythema intertrigo* the folds in the area under consideration are only liable to attack in common with folds in other parts. The diagnosis of these affections has been given elsewhere: but in diabetes eczema may begin on the penis or the vulva, and may be confined to these for a long time before spreading thence to other regions. Other conditions which may affect this area specially are: acute traumatic erysipelas, pruritus ani, small-pox in the prodromal stages, and the various forms of syphilis. In syphilis the commonest site for the moist papule is around the anus and genitalia (see PAPULES, p. 597).

Ernest Dore.

NEURITIS, OPTIC. (See OPHTHALMOSCOPIC APPEARANCES, NOTES ON, p. 517.)

NIGHT-BLINDNESS. (See VISION, DEFECTS OF, p. 920.)

NIGHTMARES may occur at any age, but they are particularly common in children between four and eight, when they may be so bad and persistent as to merit the term night-terrors.

The most common cause for a nightmare in an adult is some *indiscretion in diet*, the last meal having been taken too late in the evening, or else having contained some injudicious article. The symptom is not otherwise of diagnostic import, though some individuals, particularly those of nervous inheritance, are more liable to nightmare than others, and the tendency is certainly increased by such excitement as the reading of thrilling novels or participating in unusual events. Children are particularly prone to night-terrors during term-time, when they are working at high pressure: during the holidays the symptom often disappears. Those who are keenest upon their school work are apt to suffer most. Night-terrors may occur in these patients without any other cause than over-pressure, particularly if they lie upon the back rather than upon one side during sleep: but the tendency is much increased by errors of diet, such as the eating of unripe fruit or a large late supper, by the presence of intestinal worms, and by the existence of adenoids, with or without enlarged tonsils.

Horrifying dreams may continue to harass and distress even the strongest-nerved individuals when there has been some excessive nerve-shock or long-continued nerve-strain and anxiety: the less robust the individual nervous system was originally, the less the degree of nerve-shock or exhaustion required to cause these fearful dreams. They were a marked feature of many cases of *shell-shock* after the war, especially those of the emotional rather than of the connoational type. The nightmares of shell-shock, however, need neither war nor explosives to produce them, precisely similar troubles afflicting many individuals who have *psychasthenia* from any cause—inheritance, illness, anxiety, sudden affliction, business worries, personal excesses with alcohol or in sexual matters, and so on. The nature of the dreams forms an important item in that special branch of medicine which comes under the heading of psycho-analysis.

Herbert French.

NIPPLE, DISCHARGE FROM.—(See DISCHARGE FROM THE NIPPLE, p. 227.)

NODULES in ordinary dermatological terminology are solid elevations larger than a papule and smaller than a tumour; the definition, however, makes no pretence to scientific exactitude. Nodules differ from papules not only in size but also in their greater tendency to downward growth; the substantial difference between a nodule and one of the larger papules is that the one is a solid lesion extending upwards, while the other is a solid lesion projecting both upwards and downwards. They may be neoplastic, or hypertrophic and inflammatory.

Little need be said here of the nodules met with in some malignant diseases, for the differential diagnosis of carcinoma and of sarcoma will be found under **TUMOURS OF THE SKIN** (p. 886). Fibroma, myoma, and cysts are also dealt with under this heading, and glands in the article on **PUSTULES** (p. 681).

The nodules of *lupus vulgaris*, arising in either the superficial or the deep part of the corium, are soft, brownish-red, and translucent, resembling apple jelly. At first buried in the skin, they presently appear as discrete papules the size of a pin's head, arranged in groups or in irregular circles, dull red at the outset, but afterwards pale. Gradually the papules develop into nodules, the intervening skin meanwhile becoming thickened by cellular infiltration, reddened by inflammatory stasis, and raised into a patch which is covered with fine branny scales. Around the edge of the patch new nodules spring up, and eventually a large area of skin may be invaded. The patch may undergo slow involution and be followed by scarring; but much more often ulceration occurs, the sore being covered with a greenish-black crust, around the ragged edges of which will be seen apple-jelly nodules in various stages of development. In parts like the nose there may be necrosis of cartilage, but there is never erosion of bone. The apple-jelly nodule is the chief diagnostic feature of *lupus vulgaris*. In typical cases the patch with its infiltrated, raised surface, its well-defined edge studded with the nodules, and its covering of fine scales, can hardly admit of misinterpretation. Less typical cases may require to be differentiated from *lupus erythematosus*, rodent ulcer, epithelioma, scrofuloderma, and syphilis. *Lupus erythematosus* begins as minute red points, not as dull-red papules, and the lesions never develop into apple-jelly nodules, nor do they ulcerate or extend to the deeper parts and erode cartilage. They are symmetrical in distribution, as *lupus vulgaris* scarcely ever is, and the affection seldom appears before puberty, as *lupus vulgaris* almost invariably does. It is only when the lesions peculiar to *lupus vulgaris* are masked by œdematous swelling that the two affections can be confused; but if the skin at the spreading edge be stretched, small amber-coloured nodules can usually be seen.

In *rodent ulcer* there is usually but one lesion, which runs a much more sluggish course than the nodules of *lupus vulgaris*; the ulcer has an indurated border and a firm base, and penetrates deeply into the tissues; and the disease is essentially one of later life (see **ULCERATION OF THE FACE** (p. 891). *Epithelioma*, again, is a disease of later life. The hard, everted edge of the growth, the foul base, frequently roughened with warty formations or sprouting with cauliflower-like excrescences, the implication of neighbouring glands (which very occasionally, however, occurs in *lupus*), and the secondary deposits, form quite a different clinical picture from that of *lupus vulgaris*.

In one form of *scrofuloderma* nodules develop under the skin, and an ulcer is formed which is bordered by dark-bluish, thin, undermined skin that has too little vitality to allow of repair; there is no infiltration as in *lupus vulgaris*, the nodules do not present the apple-jelly aspect, and other evidences of the disease will be found on the neck or elsewhere, in the form of enlarged glands or scars. As, however, the two conditions frequently co-exist, and the treatment is virtually the same, diagnosis between the two is of little practical importance.

In the diagnosis from '*lupoid*' tertiary syphilis, again, the apple-jelly nodule of *lupus vulgaris* plays the chief part. The syphilitic process, further, is much more rapid, nor is acquired syphilis generally a disease of early life. The nodules and ulcers of late syphilis, growing by infiltration of the surrounding parts and often breaking down into ulcers prone to become serpiginous, and showing little tendency to spontaneous cure, have in turn to be differentiated from other conditions. They may be mistaken for abscess, but if opened they give issue not to pus but to a gummy liquid. If the ulcer into which the gumma breaks down be on the leg, it may resemble callous ulcer, but its obduracy to ordinary treatment and its response to the iodides will reveal its true nature.

Wassermann's serum test will probably be positive. From syphilitic ulcer rodent ulcer differs in its hard edge, and red, shining, dry floor, as well as in its favourite situations; epithelioma, in that a process of new growth has preceded the ulceration; scrofuloderma, in the undermined border of the ulcers and the slow rate of the process.

In *yaws*, as in syphilis, the nodule is the most characteristic lesion of the tertiary stage. It arises in the subcutaneous tissue, and generally leads to the formation of superficial ulcers which spread serpiginously, like the ulcers of tertiary syphilis. New nodules frequently appear in the neighbourhood of the older ones, and masses resembling syphilitic gummata may form and break down into ulcers. These late ulcers mostly appear on the lower part of the leg, especially around the ankle, but they are not uncommon about the lips, and indeed may occur in any part of the body. The clavicle, sternum, ulna, tibia, and the metacarpal and metatarsal bones, are often the sites of nodules which may occasion permanent thickening, or break down and cause ulcers. Between yaws and syphilis there are obvious resemblances in the tertiary stage, but there are marked differences in the primary and secondary stages. In yaws the inoculation lesion is not indurated, there is seldom distinct glandular enlargement, the mucous membrane lesions of syphilis are absent, and the most characteristic lesion, which appears in the secondary period, is the frambesial granulomatous excrescence known as the yaw (see SCABS, p. 742). In yaws, the exanthem, the alopecia, the iritis, the affection of the permanent teeth, the bone lesions, the polymorphism, the nerve lesions, and the gummata of syphilis are wanting. Yaws is never hereditary nor congenital; yaws and syphilis confer no immunity against each other, and yaws may die out in a community while syphilis remains, or it may be universal in a community where syphilis is unknown. The minute histology of the lesions of the two diseases also furnishes important differences.

From *tuberculosis* yaws differs in the absence of the tubercle bacillus and of the characteristic tuberculous architecture with its giant cells and daughter plasma-cells, more marked disintegration of the fibrous stroma, and complete disappearance of the blood-vessels. The *Treponema pertenue* (Castellani) may be found in scrapings from the papules.

In *leprosy* the nodule (Fig. 388) marks one of the three types of that affection, the others being nerve or anæsthetic leprosy, and mixed or complete leprosy. In nodular (or tubercular) leprosy the macules, which are always the primary lesion, are transformed into nodules by sudden increase of inflammatory infiltration. When fully developed they vary in size from a small shot to a filbert, or larger, are round or oval, but raised considerably above the level of the skin. They may mimic lupous nodules, syphilitic papules, rosacea, erythema nodosum, or sycosis. Sometimes telangiectases may be observed on their surface. They are elastic to the touch, are at first sometimes hyperæsthetic, but later very frequently become temporarily or permanently anæsthetic. Nodules on the mucous membranes are red or grey, and may resemble syphilitic lesions. Both on skin and on mucous membrane they tend to break down, but in exceptional cases they either undergo cicatricial shrinking or reach the ulceration stage by way of suppuration. The differential diagnosis of leprosy in the macular stage is given under MACULES (p. 478). In the later stages the identification of the disease seldom presents difficulty. The nodules of leprosy may resemble those of lupus vulgaris and the tubercular syphilide, but the

FIG. 388. A typical case of nodular leprosy in a Norwegian.
(Chc. Dr. Armand Hansen.)

lupous and syphilitic eruptions are both of limited extent, and there is no anaesthesia. The syphilide also is serpiginous, or occurs in crescentic groups. Wassermann's serum test may be positive in leprosy without syphilis, and therefore cannot be relied on in differentiating the two. In the early stages of nodular leprosy the lesions may strongly resemble those of *erythema nodosum*, and, as in that affection, there may be pains about the joints: but if the case be one of *erythema nodosum* the nodules will disappear within a fortnight, though successive crops may arise for three or four weeks longer. Preceded and accompanied by pains about the joints, by pyrexia and other symptoms of constitutional disturbance, oval nodules, ranging in size from a walnut to a hen's egg, appear on the legs and feet and, less frequently, elsewhere. They are most common on the front of the legs between the knees and ankles, next between the wrists and elbows. In colour they are first bright red, but soon become bluish in the centre and purple at the periphery, exhibiting as they subside the changes of tint presented by a bruise. *Erythema nodosum* is an affection of adolescence, and girls are attacked by it twice as often as boys. There is nearly always considerable pyrexia, and acute osteomyelitis of the tibia may be suspected if it is not remembered that *erythema nodosum* is nearly always bilateral, which osteomyelitis seldom is. There is never ulceration, and this, with the pains and swellings about the joints, distinguishes it from syphilitic nodules. The same features distinguish it also from an *erythema of the legs*, the result apparently of excessive standing, to which young girls are sometimes subject, and from the node-like swellings which sometimes occur in the legs of women suffering from *varicose veins*.

The absence of ulceration and the presence of joint-pains are points which differentiate *erythema nodosum* from *erythema induratum scrofulosorum* (Bazin's disease). Here the nodules, which occur chiefly on the calves of the legs, are at first subcutaneous, and can be felt rather than seen. They are generally discrete, but may become fused together into a solid, infiltrated mass, and are apt to break down into irregular ulcers. They differ from the nodules of *erythema nodosum* not only in the features already noted, but also in colour, being violet instead of bright red, and not undergoing successive bruise-like changes of tint. From gummata they differ in being less painful and in running a less rapid course, as well as in being more numerous, and in attacking both legs. The nodules of *erythema keratodes* differ from those both of *erythema nodosum* and of *erythema induratum scrofulosorum* in that they appear only on the back of the finger-joints, while on the palms and soles there is overgrowth of the horny tissue, accompanied by oedema and tenderness.

The condition which Boeck designated *multiple benign sarcoid*, or *miliary benign lupoid*, presents some resemblance to lupus and sarcoma. The nodules, at first rose-coloured, afterwards become livid, then brownish. In size they vary from a millet seed to a large bean. The favourite sites of the eruption, which is always symmetrical, are the face, shoulders, wrists, and the extensor surfaces of the upper limbs: but exceptionally the scalp, the back, and the lower limbs are attacked. Occasionally the lymphatic glands

enlarge. The nodules never break down, but after a period, it may be of several years, they shrink and disappear, leaving a slight atrophic scar. The affection, which often accompanies visceral tuberculosis, is distinguishable both from sarcoma and from lupus vulgaris by histological examination, as well as by the course it runs. From the latter affection it is distinguished also by the negative reaction in inoculation experiments.

The subcutaneous nodules of *acute rheumatism* generally occur over the sheaths of tendons and the fascia covering bony prominences, around joints, and on the scalp. They may be as small as a pin's head or as large as a bean. Within limits they can be made to glide on the underlying tendon-sheath or fascia. They are sometimes met with in adults whose hearts have not been damaged by the toxæmia, but much more frequently in children with distinct valvular lesions, and according to some authorities they are analogous to, if not identical with, the nodules that have been found post mortem on the borders of the mitral curtain and in the myocardium Aschoff's nodes. The coincidence of nodules such as these with rheumatic fever can leave no doubt as to their true nature. *Heberden's nodes* (Fig. 336, p. 427), the little knobs on the finger-joints which are caused by osteophytic outgrowths from the bases of the distal phalanges in certain elderly persons, are unmistakable, and the same applies to the nodular pads which sometimes develop on the backs of the knuckles (Fig. 343, p. 431). Multiple subcutaneous

cysticerci are a rarity the diagnosis of which may be suggested by the eosinophilia, but it can only be clinched by the excision and microscopical examination of one of the nodules.

Multiple nodules in the subcutaneous tissues, but causing visible projection of the skin, are a feature of *Recklinghausen's disease*; sometimes the distribution is definitely along the course of main sensory nerves, especially in the limbs; in the trunk the nerve distribution is less obvious. Each nodule is a neuro-fibroma, a neuro-lipoma, or a neuro-fibro-lipoma; and in case of doubt histological examination may be required to clinch the diagnosis. The malady is very chronic, extending over years; but ultimately there may be thousands of these nodules beneath the skin of the limbs and trunk. Sometimes they are very painful, but they may be painless. The diagnosis is generally obvious at once.

Ernest Dore.

NOISES IN THE EARS. (See TINNITUS, p. 877.)

NOISES IN THE HEAD are complained of by two entirely different classes of patient, namely: (1) *The insane*; and (2) *The sane*.

1. **The Insane.** In these cases the noises may be of indistinct or indeterminate nature, but more often, in addition to mere noises, buzzings, singings, roarings, hootings, there are more definite subjective auditory sensations, which as a rule take the form of voices. They then constitute a variety of either hallucination or delusion—the former if there is some organic mischief at the bottom of sounds which are misinterpreted, the latter if the voices are pure fancy. In either case the hearing of the voices needs to be persistent to constitute evidence of insanity, for most normal persons have transitory subjective sensations of having been spoken to when they are quite alone. If, however, the patient persistently hears voices when there are none, other evidence of insanity should be looked for, though it often takes an expert psychologist to detect the nature of the mental malady. The voices may appear to the patient to be definitely within his own head; on the other hand, they often appear to be external voices, sometimes strange to the patient, sometimes familiar; attributed perhaps to a non-living person, a dead wife, or God, or Christ; perhaps to a living person who is far away—a straying daughter, an old friend, a loving mother. The voices may say different things at different times, or they may constantly reiterate the same sentence; in the worst cases they urge the patient to this or that particular action, especially suicide or homicide. When they have reached this degree there can be little doubt as to insanity. They do not, however, belong to any one type of insanity; they may occur in melancholia, accusing the patient of having committed the unpardonable sin and urging him to suicide; or in mania, urging to homicide for some supposed wrong; or in general paralysis of the insane; or in the melancholic or maniacal phases of *folie circulaire*. The chief difficulty in diagnosis arises in the early stages, or when a patient hears diffused sounds of subjective origin, due perhaps to organic causes, but feared by the patient to be a sign that he is going mad. In such cases much discretion may be required in deciding the psychological import of the noises complained of.

2. **The Sane.** Perfectly sane persons may be bothered tremendously by subjective noises in the head—sensations resembling the blowing off of steam by railway engines; crackings and groanings; hissing or buzzing noises; rhythmical pulsating noises; clatterings and dins like hundreds of drums beating at one time; roarings; hammerings, and so on. As a rule it is possible, on careful inquiry from the patients, to differentiate these into two main types—namely: (1) Those in which the noises rapidly wax and wane, though they are never absent, the variations having a more or less rhythmical character related to the pulse-rate; and (2) Those in which there is no such rhythm in the subjective noises heard. The former group comprises cases in which the fault lies either in the blood itself or in the cerebral vessels through which it flows; in the latter group the cause usually lies in the ear itself—external, middle, or internal—or in the hearing centre in the temporosphenoidal lobe of the brain. In either case the patient may live for years, and get used to the troublesome noises; general hearing may be quite good in spite of them; and it is often very difficult to be quite certain of their cause because there is so little post-mortem evidence to base their pathology on.

The hæmic and vascular conditions to think of in connection with the first group are the following :—

- Arteriosclerosis: Granular Kidney.* Evidenced by high blood-pressure readings with the sphygmomanometer and by albuminuria.
- Aortic Regurgitation.* Evidenced by the aortic diastolic bruit and the highly pulsatile arteries generally.
- Atheroma of the Cerebral Arteries.* Guessed at on account of the age of the patient and the condition of the thickened radials and the tortuous temporal arteries: there need be no increased systemic blood-pressure.
- Severe Anæmia* (see ANÆMIA, p. 25). Any condition of severe anæmia may cause noises in the head, but it is most marked in cases of pernicious anæmia, severe chlorosis, and anæmia due to severe blood loss—for instance, post-partum hæmorrhage, bleeding of a duodenal ulcer, hæmatemesis, or hæmoptysis.
- Graves' Disease* (p. 283). In which all the arteries may be pulsating very violently.
- Purely Functional Conditions, with or without Hysteria.* Especially when there is also undue pulsation of the abdominal aorta (p. 662), great exaggeration of the knee-jerks, visceropptosis, or mobility of the right kidney: in many such cases the diagnosis would be psychasthenia or nerve-exhaustion rather than hysteria.
- Toxic Conditions.* Especially intestinal toxæmia from any form of chronic constipation: or from chronic sepsis of the tonsils, uterus, teeth, the condition of the latter being recognizable, sometimes, only by X-ray examination: or from alcoholism, acute and chronic: or from the effects of certain drugs, especially salicylates, aspirin, quinine, arsenic, iodide of potassium, plumbism: or hypnotics such as bromides, acetanilide, phenazone, pyramidon, opium, morphia, omnopon, heroin, luminal, medinal, sulphonal, trional, dial: or in chronic cocaine cases: or the effects of fumes due to coal gas, lime kilns, coke fires, petrol exhausts, or the products of certain trades such as brick-making, soap-boiling, glue-making.

When these causes can be excluded, and there is reason to think there is or has been trouble in the ears themselves, the various conditions that need to be considered are:

- Wax in the ear.
- Inflammation of the external auditory meatus.
- Blows upon the ear.
- The effects of work carried on amid exceptional circumstances of noise, e.g., boiler-makers, riveters: or under exceptional conditions of external pressure, e.g., under high pressures: divers, caisson workers, workers in very deep pits: or under low pressures: mountaineers, those who live at high altitudes, balloonists, airmen who ascend to great heights.
- The effects of chronic otitis media (otosclerosis), generally preceded by OTORRHOEA (p. 521).
- Chronic thickening of the bones containing the ears: e.g., as part of osteoporosis, osteitis deformans (p. 194), acromegaly (p. 293), chronic syphilis of the bones, leontiasis ossea.
- Chronic thickening of the meninges in relation to the petrous bone: secondary to otitis media: due to injury, chronic alcoholism, age, or syphilitic pachymeningitis.
- Tumour, abscess, or inflammatory changes affecting one temporosphenoidal lobe.

When the noises in the head are due to ear trouble they are likely to be much more marked upon one side of the head than the other: when due to vascular or hæmic states they are more likely to be symmetrical: this general rule, however, is liable to exceptions (q.v.), and in all cases a full examination of the ears is necessary, especially by means of the aurial speculum and by the tests for hearing described under DEAFNESS (p. 205). Some of the conditions mentioned in either of the main groups above may be associated with vertigo, so that the latter is not so useful a symptom in the differential diagnosis as might be supposed. Upon the whole, however, it is true that vertigo is to be expected more with either local ear conditions or with arteriosclerosis than with any of the others, so that in a case in which vertigo is prominent but the blood-pressure is not raised, the probability of some local affection of the outer, middle, or internal ear, especially perhaps of the semicircular canals, will be considerable.

The Wassermann reaction should be tested in all cases in which there is any hesitation in the diagnosis: if it is positive a syphilitic cause will be likely, and it is surprising how many nerve symptoms of obscure origin are really syphilitic—sciatica, for example, is another instance.

The great majority of patients who complain of noises in the head are adults, and most of them are past middle age. The symptom is quite uncommon in children.

NOSE BLEEDING. (See EPISTAXIS, p. 273.)

Herbert French.

NOSE, DISCHARGE FROM.—(See DISCHARGE, NASAL, p. 223.)

NOSE, REGURGITATION OF FOOD THROUGH.—(See REGURGITATION OF FOOD THROUGH THE NOSE, p. 730.)

NUMBNESS. (See SENSATION, SOME ABNORMALITIES OF, p. 747.)

NYCTALOPIA. (See VISION, DEFECTS OF, p. 920.)

NYSTAGMUS. Several varieties of associated tremor of the two eyes are comprised under the term nystagmus. These are : (1) Searching movements ; (2) Pseudo-nystagmus ; and (3) Nystagmus proper.

1. Wide purposeful and slow movements of the eyes in all directions are usually seen in people who are born blind or have lost the power of fixation as the result of some lesion of the retina or choroid at the yellow spot. The eyes appear to be seeking for something but never rest on any definite object.

2. Pseudo nystagmus, which is commonly confused with true nystagmus, is the term applied to rapid jerking movements of the eyes when they are carried to the extremity of an excursion in any direction. The eyes, instead of remaining fixed on the object, rapidly recede from their position and return to it at the rate of four or five oscillations a second. This condition is a characteristic symptom in *Friedreich's* or *hereditary ataxy*, in *disseminated sclerosis*, and in many cases of *cerebellar tumour*. For the differential diagnosis of these conditions see PARAPLEGIA, p. 621.

3. Nystagmus proper is the term applied to the condition in which the eyes make rapid regular oscillations about a fixed point, not only at the extremity of an excursion, but when the eyes are otherwise at rest, and looking directly forward. The oscillations may be in the vertical or the horizontal meridian, or may in some cases exhibit a rotatory or circular movement. The condition is usually bilateral, though it is occasionally met with affecting one eye only, and in some rare cases the character of the nystagmus may differ in the two eyes.

True nystagmus is caused by :

a. Conditions causing defective vision in the early months of life. As a result of such affections, the macular region is not differentiated from the surrounding portions of the retina as is the usual course in the early months of infant life, and power of fixation is never acquired. Conditions which may thus cause nystagmus are *ophthalmia neonatorum*, *congenital cataract*, *colour blindness*, *albinism*, and certain cases in which there is an unusual distribution of the retinal pigment. The diagnosis of these various conditions depends on an accurate examination of the eye.

b. Conditions developing in later life due to constant strain from peculiar occupations, as for example *miners' nystagmus*, in which it is probably caused by continued work in a dim light, where the central vision necessary for steady fixation is comparatively ineffective, and in which it is associated with other symptoms of failure of the central nervous system. As a rule it improves on the cessation of the occupation which causes it.

c. *Aural irritation*, in which it is usually associated with vertigo.

d. In certain cases of *cerebellar tumour* it is a marked symptom.

e. After certain forms of injury to the head, after air-crashes, railway accidents, motor-car smashes.

f. As the result of certain chronic poisonings, notably manganese ; it is met with amongst those who work at manganese-ore mines ; it may also result from plumbism.

g. Syringomyelia, very occasionally.

Herbert L. Eason.

OBESITY implies an excessive accumulation of fatty tissue in the body. It is not necessarily pathological, but it ultimately incommodes even persons who are otherwise healthy, and it is liable to lead to cardiac symptoms due to fatty changes in and around the heart. The following are some of the chief causes :

Heredity
Continued over-eating
Continued drinking of malt liquors
Too little exercise
A pre-glycosuric state
Chronic parenchymatous nephritis
Testicular atrophy or excision

Ovarian insufficiency
Hypothyroidism and myxœdema
Hypopituitarism
Cerebellar tumour
Hypernephroma
Adiposis dolorosa or } Dercum's disease.
Diffuse lipomatosis }

The majority of the above need little discussion. Families in which all the members tend to run to fat are familiar enough: the individuals may weigh anything from 16 to 30 stone without necessarily being ill. Over-eating, over-drinking, and under-exercising are generally obvious

Fig. 389.—A case of hypothyroidism, short of typical myxedema. Great benefit accrued from thyroid medication.

Fig. 391. A case of myxedema of a young woman, showing the malar flush, the yellowish coloriness of the rest of the face, and the baggy swelling of the eyelids. (*Lancet*, 1923.) The nose and lips are not so coarse looking as in sometimes the case.

Fig. 390.—Another type of case of hypothyroidism, short of typical myxedema, in a great benefit accrued from thyroid medication.

if the patient's mode of living is known. The *pre-glycosuric state* is particularly important from the point of view of life insurance: when a young man or woman under thirty begins to run to fat without apparent cause there is some error in his metabolism; there may be no glycosuria at this time, but in quite a number of such cases the error of metabolism develops as time goes on, until presently there is glycosuria, and finally typical diabetes mellitus.

Chronic parenchymatous nephritis sometimes gives rise to a large, pale person, who looks, and is, fat and flabby. Part of the apparent fatness may be due to excess of fluid in the tissues, but there need be no obvious oedema with pitting on pressure. There may or may not be a history of previous acute nephritis: some of these cases arise insidiously. The diagnosis is not difficult where renal tube-casts and an abundance of albumin are found in the urine, particularly if there is a big heart, a prolonged first sound at the impulse, a ringing aortic second sound, a high blood-pressure, and perhaps albuminuric retinitis.

Testicular atrophy or excision as a cause for undue fatness is best exemplified by eunuchs; similar fat accumulation sometimes occurs in less degree as the result of atrophy after bilateral gonococcal orchitis or epididymitis, or similar trouble due to mumps; it does not follow tuberculous destruction, for the patient then wastes instead. Palpation of the scrotum may indicate the diagnosis.

Fig. 392. From the same patient as *Fig. 391.* The upper eyelid shows a more than ordinary degree of the myxedematous changes which is the result of the excess of subcutaneous tissues, giving an overhanging appearance to that part of the eyelid which lies between the eyebrow and the free margin of the upper eyelid.

Fig. 393. From the same patient as *Fig. 391.* The hand, though that of a young woman, shows multiple fine wrinkling of the surface and a general bulged appearance different from that which would be due to mere fatness. The bulginess of the fingers is further indicated by the way in which the rings, formerly large enough to fit easily, now constrict the finger and cannot be drawn off.

Ovarian insufficiency is probably a potent cause for undue stoutness in certain women, but it is difficult to prove this because many of the patients suffer from hypothyroidism at the same time; there is a close inter-relationship between the thyroid gland and the ovaries. Only a small proportion of those cases in which both ovaries have been excised become obese; but when the normal ovarian activities are beginning to abate, especially at and immediately after the menopause, it is common for women to become very stout. They are apt to develop peculiar nervous symptoms at the same time, and it is noteworthy how both the latter and the obesity may be relieved by relatively small doses of thyroid extract; such cases may be termed sufferers from hypothyroidism (*Figs. 389, 390*), even in the absence of the typical signs of complete myxedema (*Figs. 391, 392*)

increasing stoutness, loss of strength, broad features, increasing slowness of the intellect, broadening and thickening of the fingers and hands (*Fig. 393*), malar flush (*Fig. 391*),

and falling out of hair and eyebrows. The best test of the diagnosis is the effect of administering carefully graduated doses of thyroid extract.

There are certain boys and girls—especially boys—who tend to become enormously fat long before they reach the age of puberty—the Fat Boy of Peckham type. This abnormal development of fat and size is in some instances associated with an affection of a suprarenal capsule or of

Fig. 394.—A girl, age 6, suffering from hypernephroma, which proved fatal from secondary deposits in the lungs: the photograph shows the premature development of pubic hair, which in this case appeared at the age of eighteen months.

Fig. 395.—The same case as Fig. 394 after removal of the pubic hair: showing the hypertrophy of the external genitalia, without development of the breasts.

Fig. 396.—A case of dystrophia adiposogenitalis due to dyspituitarism: note the general fatness, the hypertrophy of the mamma, and the smallness of the penis. A normal boy of the same age is partly in view in the left-hand illustration.

a kidney *hypernephroma*. The latter affection does not always cause this overgrowth, however, for in another type of patient the tumour leads merely to premature development of the pubic hair and external genitalia. Figs. 394 and 395 are from a girl, age 6, who had had thick pubic hair since she was eighteen months old. The clitoris was enlarged, but there had been no menstruation. The diagnosis was confirmed post mortem, the congenital suprarenal tumour producing secondary deposits in the lungs after six years. Obesity of the type shown in Figs. 396, 397 is generally due to *affections of the pituitary body*. Over-activity of the anterior lobe of the pituitary causes acromegaly

(hyperpituitarism) (p. 293) : deficient activity (hypopituitarism) in either the anterior or the posterior lobe results in an error of metabolism which affects not so much the bones as the soft parts, with obesity associated with backwardness of development of the sexual organs ; and, in the male, a stout feminine type of development. The diagnosis suggests itself when, along with increasing and clearly pathological fatness, there is persistence of the infantile type of intellect, voice, and genital organs, abundant stools, and a proneness to sleep much. A skiagram of the skull, taken laterally, may confirm the diagnosis by demonstrating an abnormal sella turcica (*Fig. 310*, p. 379). The intracranial lesion need not be primarily in the pituitary body itself ; a tumour at a distance from the latter can sometimes so interfere with it indirectly that the same kind of symptoms may result as if the pituitary gland were the chief focus of disease ; this may be the explanation of the fatness that is often observed in cases of *cerebellar* or *cerebral tumour*.

Fig. 397. Pathological obesity due to dyspituitarism. The patient was 22 years of age, and apart from his excessive weight was in good health. A skiagram of the skull showed a shallow pituitary fossa similar to that illustrated in *Fig. 309*, p. 379.

Fig. 398. A case of *adiposis dolorosa* (Dercum's disease) of Turkish-trouser type. Note the smallness of the hands and feet in contrast to the excessive fatness of the arms and legs.

Adiposis dolorosa, *diffuse lipomatosis*, and *Dercum's disease* (*Figs. 398-404*) all seem to be closely related. There are two types—the alcoholic and the congenital syphilitic ; the former is the commoner, and occurs in older patients than does the other. Extreme fatness develops, but not quite universally ; the abdominal wall, especially on either side of the umbilicus, the neck, shoulders, arms, forearms, thighs, and legs may become enormous, but the hands, feet, scalp, ears, nose, and forehead escape. The patient's muscular power, tested by the dynamometer, is very small, sometimes not a tenth of the normal ; and when any of the fat parts are taken hold of firmly, without any pinching or other procedure that would be unpleasant to an ordinary patient, some of these cases experience acute pain—the name *adiposis dolorosa* describing the two main symptoms of the malady. There are often mental symptoms at the same time ; a patient of thirty may periodically imagine she is only eight, and behave and speak as though

for the time being she were a child again ; and so on in other cases, the types of mental symptoms being protean. Superficially these cases may simulate myxœdema, but a

Fig. 399.—A case of Dercum's disease at the age of 5, before the symptoms of adiposis dolorosa developed. (Compare *Figs. 400-402.*)

Fig. 400.—Dercum's disease : the same case (on right) as *Fig. 399*, at age of 13, sitting beside her normal sister, age 11 (on left). (Compare *Figs. 401, 402.*)

moment's observation will show that there is no affection of the hands and feet, which are just the parts to be first broadened and thickened by myxœdema, besides which thyroid treatment does not bring about material improvement.

Herbert French.

OBSTRUCTION, INTESTINAL. (See CONSTIPATION, p. 158 : VOMITING, p. 927.)

OCHRONOSIS. (See URINE, ABNORMAL COLORATION OF, p. 902.)

CEDEMA, ASYMMETRICAL. Edema of one leg or arm, or of some local part of the head, face, neck, or trunk, may be due to any of the following causes :

Congenital :

- Constriction by amniotic bands
- Communications between arteries and veins.

Acquired :

- Blockage of veins from *within*—non-infective thrombus, varicose veins, infective thrombus, e.g., white leg ; by pressure from *without*—by glands, tumours, aneurysms, etc.

Osteomyelitis of a long bone

Blockage of lymphatics, e.g., in cellulitis, or other local inflammation ; filariasis

Artificial, by ligature

Drug edemas, such as those caused by aspirin, antitoxic sera, iodides, bromides, mercurials ; and any which cause urticarial lesions (p. 934)

Angioneurotic edema.

Congenital Causes are rare, but as a rule they are identified easily.

Acquired Causes. The diagnosis may be obvious : For instance, there may be toothache with unilateral edema of the face, or a scalp wound with boggy swelling all round it, or a well-marked *cellulitis*, with red streaks extending up the limb showing the course of acutely inflamed lymphatics. Cellulitis presents difficulty in recognition only when the inflammation is not very acute, and when there is no obvious source of infection, such as an abraded toe or a suppurating wound of a finger. Cellulitis may then be confounded with gout ; but the history, the leucocytosis, and the absence of other gouty manifestations will indicate the former. There may be considerable pyrexia in acute gout (Fig. 330, p. 424), so that the temperature chart does not serve to distinguish it from cellulitis.

Varicose veins are a frequent cause of asymmetrical edema, especially in the leg, and if there is thrombosis as well marked swelling results. The thrombus, however, does not

always lie in a superficial vein, and if it is in a deep one such as the popliteal, femoral, or iliac, the case may not be so clear. The thrombus in these cases is often due to septic infection, and the common source is sepsis in connection with the uterus following parturition—white leg; or it may arise during a prolonged febrile illness such as typhoid fever, or in a case of cachexia resulting from malignant disease or other prolonged and debilitating malady, or from one of the blood diseases such as leukaemia.

Fig. 405.—Persistent edema of left arm consequent on the radical operation for the cure of carcinoma of the breast, with clearance of the lymphatics in the axilla.

When none of these causes is present it is necessary to examine carefully to ascertain whether there is any *swelling pressing on and obstructing the veins*, such as an aneurysm in the popliteal space or a mass of malignant glands in the pelvis; and not only must the whole limb be examined, but also the rectum, vagina, and lower part of the abdomen, and the neck and upper thorax, in the case of the leg and arm respectively. For instance, there may be a tumour springing from some structure in the pelvis causing pressure on the iliac veins; swelling of the arm may be caused by an aneurysm, subclavian or thoracic, or by a mediastinal new growth, in which case X-ray examination may be of material assistance in verifying the cause. (Edema due to venous obstruction pits readily on pressure, but where the lymphatics are blocked the edema is much more solid; this may be an important diagnostic point.

Osteomyelitis.—In some obscure cases the cause of the edema lies in deep-seated pyogenic infection of a bone. The difficulty of diagnosis may be particularly great in the case of the femur, which is covered so thickly by muscles. The edema in these cases is accompanied by more or less cellulitis and secondary blockage of lymphatics, and the general appearance of the leg may suggest venous thrombosis when the actual lesion is much more grave. Rigors are suggestive of more than thrombosis. The diagnosis may be cleared up by means of a skiagram if the patient's condition allows of one being taken. Sometimes it may be decided to operate to settle the doubts.

Elephantiasis due to blockage of lymphatics by the parasite *Filaria sanguinis hominis* is not common in England, though a pseudo-elephantiasis, due to long-standing lymphatic obstruction with resulting roughening, thickening, and fibrotic changes in the skin and underlying tissues, is not uncommon, and may result from long continuance of a tumour, or be associated

badly-united fracture, or follow some operation in which lymphatics have been removed, e.g., after amputation of the breast and axillary contents for carcinoma (Fig. 405). Probably the most difficult group of all cases to diagnose is that in which there is a thrombus of one of the deep veins of the leg without any obvious disease, and in this event the diagnosis can only be arrived at by a process of exclusion. **Milroy's disease** (Fig. 406) is diagnosed from the family history (see p. 516).

Ligature. It sometimes happens that a patient, generally a female, presents herself with an edema of a limb for which no explanation can be offered. It has to be borne in mind that there are some neurotic individuals who will tie a ligature round their limbs in order to simulate disease or to excite sympathy, and who have even gone so far as to suffer amputation. It is often extremely difficult to detect the fraud; but if the possibility be suspected the nurse in charge must be instructed to keep watch, and at unexpected times to search the patient, when a handkerchief or a piece of string may be found constricting the limb. The fact that the

Fig. 406. Milroy's or Meigs's disease. A case of unilateral hereditary trophoedema of the leg. The condition had developed spontaneously in a girl who had never been out of England, and who suffered little inconvenience from the affection. She was 21 when the photograph was taken, and had had the swelling for years. Note that the enlargement of her right leg ceases abruptly at the groin.

upper limit of the edema is sharply defined should awaken suspicion. It may be difficult to differentiate this from *angioneurotic edema* (*Quincke's disease*), but the latter condition is, as a rule, transitory, and affects different parts of the body, e.g., the tongue, lips, eyelid, hands, etc., at different times (*Fig. 407*): the fact that the patient has had previous attacks generally points to the diagnosis, and the malady often occurs spontaneously in several members of the same family.

George E. Gask.

CEDEMA, SYMMETRICAL. Owing to accidents of posture such, for instance, as the patient sitting with one leg to the ground and the other supported upon a chair, or lying in bed turned well over to one side it is possible for edema which should really be symmetrical to appear asymmetrical. Allowing for this source of fallacy, however, the causes of symmetrical edema are different from those of asymmetrical edema (see above). One may subdivide cases into three main groups, namely: (1) *Those in which the edema is universal*; (2) *Those in which the swelling involves the face, neck, and arms, but not the legs or the lower half of the trunk*; (3) *Those in which the edema affects legs, or the legs and lower half of the trunk, but not the arms, neck, or face.*

Edema of the legs is by far the commonest type, and by far the most important point in the diagnosis is to decide as soon as possible whether this edema is due to Bright's disease, heart failure, or to some other cause. The broad distinction into these groups is seldom difficult. The urine should be tested at once: if albumin is present, microscopic examination for renal tube-casts is essential, their presence indicating renal mischief, their absence probably excluding it, unless the renal lesion is very acute, in which case there will be renal epithelial cells even if there are no tube-casts: if there is no albumin in the urine, renal disease as a primary cause of edema of the legs is unlikely, though not impossible.

It will be easy as a rule to decide whether there is failure of cardiac compensation or not: if there is, the differentiation between the four main groups of causes of heart failure, namely, primary valvular, primary muscular, primary lung affections, and primary arterial or renal conditions, will be made upon the lines indicated upon p. 17.

Other causes for edema of the legs will be suggested by other symptoms in the case or by the history, but they cannot be diagnosed with certainty until both renal disease and heart failure have been excluded. It seems worth while, however, to discuss in rather greater detail each of the main groups indicated above.

1. Cases in which the Edema is Universal.

When a patient has a tendency to universal symmetrical edema, the great probability is that he is suffering from either *primary acute nephritis* or *acute nephritis superposed upon chronic nephritis*; the diagnosis is indicated by the occurrence of albumin with tube-casts. The degree of edema exhibited in different regions varies, partly by reason of inequalities in the looseness of the subcutaneous tissues in different places, and partly because of the effects of gravity. Other things being equal, the edema shows most in the legs, lumbar region (lumbar cushion), penis, scrotum, labia, eyelids, and face, though careful examination may show that there is some degree of edema in every tissue from scalp to toes: it is due to the influence of gravity that when the patient is up and about the edema is most marked in the legs; is marked in the lumbar cushion and the genital organs when the patient sits propped up in bed; and is most prominent in the eyelids when the patient has been lying horizontally as during sleep.

Other causes for universal edema are rarer, but it may sometimes be due to a universal condition of *angioneurotic edema* (*Fig. 407*), though this is much more often asymmetrical; or to overloading of the tissues with fluid e.g., as the result of excessive transfusion or infusion; or in patients who have been swelling beer day after day until their bodies have become sodden. Cases due to the latter present an appearance highly suggestive

Fig. 407. Angioneurotic edema of the eyelids simulating acute nephritis.

of acute nephritis, but the absence of albumin from the urine, the history of excessive drinking over long periods, and the complete recovery when the drinking is stopped, point to the diagnosis. Generalized œdema, usually not of extreme degree, is apt to be complained of by some anæmic girls, generally between 15 and 20 years of age, often in association with gastric symptoms, especially persistent vomiting after food, and with constipation. These cases have no name; they are chiefly of importance in that they are apt to be diagnosed as nephritis, especially if there is a little albuminuria at the same time; they get well by themselves; the œdema is doubtless toxic, but whether the causal toxin is intestinal, or derived from some food source, or from temporary metabolic idiosyncrasy, no one knows. The same applies to certain cases of acute universal œdema in infancy or childhood, simulating acute nephritis, but differing from the latter in that there is no albuminuria and that spontaneous recovery takes place. Both types differ from true angioneurotic œdema in that the condition is not familial like the latter (see p. 513). Similar universal œdema, perhaps toxic in origin, but unaccompanied by any evidence of nephritis, may follow severe *gastro-enteritis* in children even when no saline infusion has been resorted to.

Certain poisons may produce universal œdema, though rarely; for instance, it is one of the effects of *snake-bite*, though as a rule the limb or other part originally bitten is very much more swollen than is the rest of the body. *Ptomaine poisoning* causes urticaria more often than anasarca, but the latter is sometimes an alternative expression of the toxic effects of this condition; and in some people, even without ptomaines, certain foods, such as shell-fish, may cause generalized œdematous swelling of the subcutaneous tissues.

Aspirin affects certain individuals in a curious way, producing urticarial wheals and universal swelling, transient as a rule, or lasting little more than twenty-four hours; though sometimes so severe that the whole face is swelled up and bloated to such an extent that the patient is for the time being unrecognizable. The symptoms appear to depend upon personal idiosyncrasy to the drug, though sometimes impurities in the latter may be the responsible factor.

Iodide of potassium may produce a similar state of affairs, especially if the drug is impure with iodates. *Arsenic* is another drug which sometimes causes universal œdema when given in excessive doses by the mouth; and organic arsenic administered intravenously in the form of 606, galyol, kharsivan, and the like, has produced phenomena similar to generalized angioneurotic œdema.

Only in very rare cases does *heart failure* produce œdema of the hands and arms as well as of the legs, and when it does so the patient usually has been ill some time, the diagnosis has been made already, and the end is not far off.

Ankylostomiasis often causes œdema of the feet, ankles, and legs, as the result partly of the severe anæmia and partly of the toxic state the patient develops; in the later phases of the disease generalized anasarca, similar to that of acute Bright's disease, is uncommon, but the nature of the malady has generally been diagnosed before this reason of the progressive anæmia, the eosinophilia, and by the discovery of ankylostomata or their ova in the stools.

Graves' disease is not commonly associated with œdema; and if it is, the swelling is generally of cardiac type and confined to the feet, ankles, and legs; sometimes, however, there may be generalized œdema with or without ascites, and the general aspect of the case may be that of an acute nephritis. Albuminuria may be present, but without tubercasts. The underlying cause may be angioneurotic in some instances. The prognosis is grave, but recovery has occurred even after the general anasarca has been extreme.

Chronic starvation, inefficient dietary, and conditions of privation or want may cause a state of chronic œdema simulating Bright's disease, but generally without albuminuria; large numbers of such cases were met with during the great war, and the condition is still spoken of as *war œdema*; the generalized œdema of exceptional cases of *beri-beri* comes in the same category.

2. Œdema of the Face, Neck, and Arms, but not of the Legs or Lower Half of the Trunk, is nearly always due to obstruction to the superior vena cava or to the main branches which go to form this, and the commonest causes of this obstruction are *thoracic aneurysm, mediastinal new growths, mediastinal gummata, chronic mediastinal fibrosis*, and

thrombosis spreading to the main trunk from, for instance, an axillary vein infected from a whitlow or from other sources of phlebitis. When the swelling comes on acutely, as it may in any of the above conditions, acute Bright's disease may be simulated on account of the extreme puffiness of the eyes; but further examination will show a remarkable limitation of the œdema to the head and upper limbs, whilst the urine will probably not contain albumin. If the obstruction to the superior vena cava persist there will presently be evidence of collateral circulation in the form of varicose veins upon the chest wall (see VEINS, VARICOSE THORACIC, p. 910).

Inflammatory lesions, instead of being asymmetrical, may sometimes produce almost symmetrical œdema of the face or neck, in which connection one may mention *erysipelas*, *cellulitis*, *anthrax*, *angina Ludovici*, the differential diagnosis of which is based upon the history, the constitutional symptoms, the local appearances of the inflammation, and the results of bacteriological examination.

Similar symmetrical swelling may be produced in the hands, or arms either by *angio-neurotic œdema* (Fig. 407), or by allied vasomotor neuroses, such as *Raynaud's disease*. Swelling of the eyes and face suggestive of œdema may sometimes be due to bouts of *crying*, prolonged attacks of *coughing*, as for instance in whooping-cough, or as the result of catarrh due to a *common cold*, *coryza*, or *measles*.

Sometimes the œdema of face, neck, and hands may have its cause in an external irritant, such as impure *soap*, or the effects of certain *waters* upon sensitive skins, or the results of *occupational dermatoses*: the nature of the latter may in some cases be obvious -- in satin-wood workers, for instance, or in gardeners planting *Primula obconica*; or it may be obscure -- the effects of peeling bitter orange in a jam factory, for instance. In most such cases, though œdema may be pronounced, erythema, the development of vesicles, and other evidence of acute dermatitis will generally be more prominent. Certain chemicals used in dyeing furs have been responsible for many curious cases of obscure œdema of the face and neck.

3. Œdema of the Legs and Lower Part of the Trunk, without any of the Neck or Face, is suggestive of heart failure or of nephritis, and the main points that arise in the differential diagnosis have been discussed above. If both these main groups of causes can be excluded, however, it is important to remember how often the legs may swell as the result of poverty of the blood in any condition of *anæmia*. This is seen commonly in cases of *chlorosis*, but is also met with as the result of any of the severer types of *anæmia*, such as *pernicious anæmia*, *lymphatic* or *splénomedullary leukæmia*, *Hodgkin's disease*, *splenic anæmia*, *pseudoleukæmia infantum*: the *anæmia* which follows loss of blood from hæmoptysis, hæmatæmesis, post-partum and other hæmorrhages: the *anæmia* that results from *parasitic infections* such as *Bothriocephalus latus*, *Tænia solium*, *Tænia mediocanellata*, *Ankylostomum duodenale*, or the effects of certain drugs; or to *cachetic conditions* such as result from carcinoma, sarcoma, syphilis, tuberculosis, starvation, malaria, and various tropical infections. The differential diagnosis of these conditions will seldom depend upon the presence of œdema alone, and each of the maladies will be found discussed under the heading of some other symptom.

Obstruction to the inferior vena cava may lead to extreme œdema of the legs: if due to *phlebitis*, the clotting of the inferior vena cava itself is nearly always preceded by that of the veins of one leg, so that even when the final result is symmetrical the history nearly always points to it having begun asymmetrically, that is to say, in one leg before the other. When the inferior vena cava is obstructed by new growth or by the pressure of ascitic fluid or a huge ovarian cyst, the diagnosis will depend upon the discovery of some abnormal mass or upon the interpretation of the cause of the ASCITES (p. 59).

The influence of the vasomotor nerves in controlling the balance of lymph production and lymph absorption in the legs is sometimes interfered with. One sees a good example of this in the œdema which develops in the lower extremities in *convalescent patients* when, having been long in the horizontal position from any cause, they first begin to walk about. It is probable that a perfectly normal person kept at rest in bed for three months would suffer from œdema of the legs in varying degree for some days or weeks after first beginning to use his limbs, and the tendency is still more marked in those who have been laid up by gastric or duodenal ulcers, typhoid fever, fractured femur, and so on. Suspicion of some kidney lesion may arise, though the absence of albumin, and the

way in which the edema disappears spontaneously in time, especially under the influence of massage, indicate the diagnosis when the history of long confinement to a horizontal position is known. Diseased conditions of the vasomotor system may produce even more marked edema, as seen in *elderly people*; in some cases of *Raynaud's disease*; in *angioneurotic edema*; in association with *peripheral neuritis*, especially in the tropical variety called *beri-beri*, an epidemic febrile illness generally seen in this country only in seaport towns as the result of an outbreak amongst seamen on board ships in which the diet has consisted largely of decorticated rice.

There is a peculiar hereditary disease in which edema of the lower extremities, occurring in many members of a family (*Fig. 408*), may be a prominent feature; in the early stages this edema is asymmetrical, affecting one leg before the other, but sooner or later both legs may become involved, until, if the family and personal history were

Fig. 408. Milroy's, or Meigs's disease. Bilateral hereditary trophoedema of the legs in a girl of 21, twelve other members of the family being affected by the complaint also. She had never been out of England. There was no abnormality above Poupart's ligament. (For a full account see Hope and French, *Quart. Jour. of Med.*, vol. 1, No. 5, p. 312.)

not known, the edema of Bright's disease might be suspected. The affection is known as *Milroy's disease*, *Meigs's disease*, or *hereditary trophoedema*. The sudden demarcation between the swollen and the non-swollen parts at the level of a joint—ankle, knee, or hip—is characteristic. There is sometimes a history of periodic acute attacks of pyrexia and of gastric disorder associated with an increase in the swelling, not altogether unlike those occurring in angioneurotic edema. The swelling may cease at the ankles in the early stages; when a subsequent spread occurs it may reach almost suddenly up to the knees, ceasing there for a variable number of years until ultimately it spreads to the groins, above which it seldom extends. The diagnosis is easy when the family history is obtainable.

Myxoedema is a condition in which the swelling of the legs may simulate actual edema very closely, and indeed in not a few cases the subcutaneous tissues of the feet and legs do pit to a certain extent on pressure. When there is actual edema as well as myxoedema considerable doubt as to whether there may not be a cardiac or other factor, as well as thyroid insufficiency, will arise. The urine often contains albumin, moreover, though generally without tube-casts. The patient is nearly always a woman of middle age (*Fig. 68*, p. 50) who has recently begun to get much stouter, and at the same time less active both mentally and physically. The diagnosis of myxoedema will be confirmed if the untoward symptoms and the abnormal state of the subcutaneous tissues disappear under the influence of thyroid medication.

It is not easy to include all the possible causes of edema in a classified list, but the following include those which have been discussed above:—

1. Universal Edema.

Primary acute nephritis
Acute nephritis as an exacerbation of chronic nephritis
Angioneurosis
Excessive transfusion or infusion
Soddening from beer drinking

Toxins (? intestinal) in girls and children
Snake-bite
Stomach poisoning
Food idiosyncrasy (shell fish)
Aspirin
Iodide of potassium
Kharsivan

Galyi
Salvarsan
Heart failure
Ankylostomiasis
Graves' disease
Starvation
War edema
Beri-beri.

2. Edema of Face, Neck, and Arms, but not of Legs.

Obstruction to the superior vena cava by:
Thoracic aneurysm
Mediastinal new growth, gumma, and fibrosis
Thrombosis

Erysipelas
Cellulitis
Anthrax
Angina Ludovici
Raynaud's disease
Angioneurosis

Crying
Coughing
Coryza
Measles
Common cold
Occupational dermatoses.

3. Œdema of the Legs, without any of the Neck or Face.

Heart failure secondary to:	Parasitic affections, especially:	Inferior vena cava obstruction
Valvular disease	<i>Bothrioccephalus latus</i>	by:
Myocardial affections	<i>Tænia solium</i>	Thrombosis
Chronic lung affections	<i>Tænia mediocanellata</i>	New growths

A Physiological Cup (*Fig. 409*) may vary in size, but usually occupies the centre of the disc. The retinal vessels dip over the edge, which is usually steeper on the nasal side, the temporal slope being more gradual. At the bottom of the cup is seen the lamina cribrosa, which is mottled by the openings through which the retinal nerve fibres pass.

A physiological cup is distinguished from that caused by glaucoma (*Fig. 428*) by the fact that it occupies only the centre and not the whole of the disc.

Congenital Crescents (*Fig. 410*) are common, and usually situated at the lower part of the disc, in contrast to myopic crescents (*Figs. 416, 417*), which are seen on the outer side. They are probably due to an uneven distribution of connective tissue in the lamina cribrosa, and are often associated with hypermetropia.

Pigmented Crescent in Disc Margin (*Fig. 411*). The disc margin is always more or less pigmented, the amount varying from a small crescent to a complete ring. The pigment has no pathological significance.

Coloboma of the Choroid (*Fig. 412*) is a congenital deficiency, and it may be recognized by its situation below the disc, the small amount of pigment at the edge of the

white area, and the presence of healthy retinal vessels on its surface. It may be associated with other congenital abnormalities, such as coloboma of the iris, optic disc, or lens.

Opaque Nerve Fibres (*Figs. 413, 414*) exist normally in the retina of some mammals, e.g., the rabbit. The condition is due to the persistence of the medullary nerve sheath of

the retinal fibres, the sheath being lost usually at the passage of the nerve fibre through the lamina cribrosa. The condition may be recognized by the brilliant white colour of the nerve fibres, the striated appearance of the white patch, and the fact that the retinal vessels are more or less embedded among the nerve fibres.

Fig. 413.

Fig. 414.

Opaque nerve fibres in the retina.

Advanced Syphilitic Choroiditis (*Fig. 415*). In advanced choroiditis the inflammatory process has

ended in the total destruction of the choroid in patches, which in some places have joined to disclose large bare white areas of sclerotic. There are large masses of pigment, usually surrounding the white areas, the pigment being chiefly derived from the choroid.

Fig. 415.

Advanced syphilitic choroiditis.

Fig. 416.

Myopic crescent of the disc.

Fig. 417.

The retinal pigment is also increased in the great majority of cases, and vision is rendered extremely defective. Macular choroiditis is degenerative in origin, and does not usually appear till middle life. It probably commences in the form of macular hamor-

rhages, which lead to degeneration and fibrosis of the macula.

The Myopic Crescent (*Figs. 416, 417*) is usually found on the outer side of the disc, and may vary in size and extent from a thin crescent to a large atrophic area surrounding the whole disc (posterior staphyloma). Usually, the size of the crescent varies with the amount of the myopia and increases with age.

Recent Optic Neuritis

(*Figs. 418, 419*) is characterized by the swelling of the disc and the blurring of its outline by retinal cedema. The retina is greyish and striated in appearance, owing to cedema

Fig. 418.

Fig. 419.

Recent optic neuritis.

between the retinal nerve fibres, and the veins are dilated and tortuous. Flame-shaped hemorrhages are also seen on the disc and in the surrounding retina, and numerous small retinal vessels on the disc, usually invisible, become dilated and apparent. In the later stages of the neuritis the hemorrhages may disappear, and the whole disc become greyer and paler, the condition ultimately terminating in post-neuritic atrophy (*Fig. 421*). The outline of the disc is lost entirely, and in severe cases the disc may be so swollen as to resemble a small mushroom in shape. Radiating lines of white patches may also be seen in the macular region, resembling albuminuric retinitis (*Figs. 423-425*).

Fig. 420.
Normal optic disc.

Fig. 421.
Post-neuritic atrophy.

Fig. 422.
Thrombosis of the central retinal vein.

Primary Optic Atrophy (*Fig. 420*) is characterized by the pallor of the disc, white or bluish-white, sharply defined lamina cribrosa, well-marked edge, and retinal vessels of normal size. In *post-neuritic atrophy* (*Fig. 421*) the disc is covered with fibrous tissue, which fills up the physiological cup; the colour is greyish-white, the retinal vessels are thin and tortuous, and the edge of the disc is irregular. In some cases of old post-neuritic atrophy or fibrosis, following slight optic neuritis, it may be impossible to distinguish the condition from primary atrophy.

Thrombosis of the Central Retinal Vein (*Fig. 422*).—In thrombosis of the central retinal vein the disc is extremely swollen and œdematous, the edge being indistinct and blurred. All the retinal veins are enormously dilated and tortuous, and the fundus is

Fig. 423.

Fig. 424.

Albuminuric retinitis.

Fig. 425.

covered with flame-shaped and petechial hemorrhages. The œdema of the retina from the obstruction of the venous circulation may be so great that the vein may occasionally be hidden entirely.

Albuminuric Retinitis (*Figs. 423-425*) is characterized by the presence of flame-shaped hemorrhages in the nerve-fibre layer of the retina, and white patches. The white patches are of two kinds. Those seen in the early stages of the disease are ill defined and woolly, scattered about the macular region in an irregular manner. These are due to exudate in the nerve-fibre layer of the retina. In the later stages, smaller white patches

may be seen usually arranged in radiating lines from the macula, which are well defined, and glistening or chalky white.

Embolism of the Central Retinal Artery (*Fig. 426*). In embolism of the central retinal artery the retina is generally pale grey or white, owing to the anaemia consequent on the obstruction of the artery. The macula itself being adherent to the choroid does not share in the general pallor, and appears as a bright cherry-red spot in contrast. The retinal arteries are extremely small, being only fine white threads in places, and the veins may be nearly empty. The optic disc is white, blurred, and indistinct.

Detachment of the Retina (*Fig. 427*).—The detached portion of the retina is silvery-grey in colour, and raised above the surrounding fundus. In cases due to serous exudate

the detached part of the retina is transparent, arranged in billowy folds, and may float about on movement of the eye. When the detachment is due to growth, the retina is usually smooth and opaque. The retinal vessels are small, very tortuous, and dark in colour.

Glaucomatous Disc (*Fig. 428*).—The excavation of the optic disc may be distinguished from the physiological cup by the

fact that it affects the whole of the disc, the edge often being surrounded by an atrophic ring. The retinal vessels bend sharply over the edge, and may disappear from view behind the overhanging margin of the disc, reappearing on the bottom of the cup. The lamina cribrosa is well marked, and the disc is white and atrophic.

Tubercles in the Choroid (*Fig. 429*) are seen as ill-defined circular masses varying in size from a dot to masses nearly the size of the optic disc. They are usually associated with miliary tuberculosis, grow rapidly, but rarely attain any great size owing to the

Fig. 426.

Hypermetropic astigmatism.

death of the patient. It is stated that they occur most commonly in the neighbourhood of the disc, but this is due to the fact that only the posterior portion of the fundus is visible with the ophthalmoscope. Post mortem they are found all over the choroid.

Hypermetropic Astigmatism (*Fig. 430*).—In hypermetropic astigmatism the disc is often oval and ill defined. The physiological cup is absent, the disc red, and the margin ill defined. The vessels may be tortuous though not dilated, and unless the error of refraction is observed, the condition may be mistaken for optic neuritis.

Herbert L. Eason.

OPISTHOTONOS is a rare but characteristic condition, in which the muscles of the neck, back, and legs are contracted rigidly in such a way that the body is over-extended in the form of an arch, supported by the occiput above and by the heels below. This position may be maintained: more often it is assumed periodically, with partial or complete relaxations between the tetanic seizures. Its chief cause is *tetanus*, but it may also be due to *strychnine poisoning*, *spinal meningitis*, *uræmia*, and *hysteria*.

Tetanus. The history will often point to the correct diagnosis. If there has been a punctured wound during the previous one to six weeks, and if stiffness of the neck muscles and of the lower jaw (lockjaw or trismus, p. 884) has set in, to be followed within a day or so by generalized rigidity, with severe paroxysmal exacerbations, the opisthotonos is almost certainly due to tetanus. The fixed smile *risus sardonius* is common to tetanus and to strychnine poisoning. An attempt will be made to obtain the drumstick bacilli from the suspected wound, very often without success. In some cases there will be no obvious wound or contusion, but although the source of contagion will then be obscure the early lockjaw and the course of the disease will point to tetanus.

Strychnine poisoning does not give rise to lockjaw, and the paroxysms of opisthotonos are separated by intervals of more complete relaxation than is the case in tetanus: there may be evidence of the source of the poisoning, either accidental, suicidal, or homicidal, in the form of a bottle, a hypodermic syringe and needle, a packet of rat-paste or vermin-destroyer, or something of that kind. In some cases the diagnosis can only be arrived at by analysis either of the gastro-intestinal contents, or of the viscera post mortem.

Spinal meningitis seldom causes difficulty in the diagnosis, for it is generally part of acute cerebrospinal meningitis, of which the general symptoms and pyrexia will have existed some days, if not a week or more, before opisthotonos is likely to occur. Optic neuritis may be found, and in some cases the bacteriological and cytological results of lumbar puncture, especially the discovery of the meningococcus, may clinch the diagnosis.

Uramic convulsions are associated with complete coma, whereas in tetanus and in strychnine poisoning consciousness is retained perfectly, the convulsions are epileptiform rather than tetanic, there is no persistent lockjaw, and the urine will nearly always contain albumin and renal tube-casts.

Hysteria sometimes takes a form that may for the moment be difficult to distinguish from tetanus or from strychnine poisoning. Unlike malingering, hysterical contractions that are even violent enough to cause opisthotonos do not always make the patient perspire, nor do they lead to fatigue in the way that similar voluntary efforts certainly would. The diagnosis of hysteria is generally arrived at by watching the case. Persistent lockjaw may be present, as in tetanus: but whereas in strychnine poisoning and in tetanus there is a great similarity between one exacerbation and the next, hysterical convulsions are apt to be polymorphous: the more the writhing and the change of attitude and position, the less likely is the attack to be organic. The mind remains perfectly clear in tetanus and strychnine poisoning, though its outward expression may be prevented by the muscular paroxysms: in hysteria, the mental attitude is in one way or another abnormal for the time being. In arriving at a diagnosis it may be of great assistance to know full details of the patient's previous history, for there may have been similar hysterical outbursts on former occasions.

OPTIC ATROPHY. (See OPHTHALMOSCOPIC APPEARANCES, NOTES ON, p. 519.)

OPTIC NEURITIS. (See p. 518.)

ORTHOPNŒA, or inability to breathe as comfortably lying down as when propped above the horizontal position, is due as a rule to a severe degree of one or other of the various causes of **DYSPNŒA** (p. 246), which see.

Herbert French.

OTALGIA. (See EARACHE, p. 252.)

OTORRHŒA. Discharge from the ear may be derived from the meatus itself, or from the middle ear through a hole in the tympanic membrane, or from the cranial cavity through tears in the meatal wall or the membrane.

Discharge due to Causes within the Meatus. *Wax* is always being secreted by the ceruminous glands, and if that secretion is more than usual it appears as a yellowish discharge; it is occasionally mistaken for a purulent discharge, especially when the wax-running has a nasty smell.

Blood escapes from the meatus as a result of wounds of its wall by blows on the ear or from damage caused by the introduction of foreign bodies or instruments, e.g., needles, pencils, toothpicks; small wounds may be self-inflicted by malingerers or neurotics. Fracture of the middle fossa of the skull may damage the bony wall of the ear and lead to bleeding from the meatus. Malignant ulceration in the meatus or middle ear also causes bleeding.

Serous discharge is frequently seen in diffuse acute eczema of the meatus, so profuse as to run from the ear. In cases of ulceration of the meatus due to diphtheria the discharge is seropurulent; this is also the case with secondary syphilitic ulceration—a rare condition.

Pus due to causes in the meatus is generally the result of boils or chronic meatitis; there is often great difficulty in deciding on the origin of pus in cases of chronic meatitis, as the membrane is hidden by marked narrowing of the canal; the absence of deafness is helpful as proving the middle ear to be normal.

In the case of boils, examination will reveal a tender swelling from which more pus can be pressed.

In a small percentage of cases of acute mastoiditis the suppuration spreads forwards through the bone and causes a swelling of the posterior meatal wall; this swelling may point and eventually burst into the meatus. When this occurs a sinus results and the appearance resembles that of a boil; this latter is excluded by the comparative absence of tenderness and by the fact that a probe can be passed into the sinus and found to enter the mastoid process.

Discharge from the Ear due to Middle-Ear Causes. This may be (1) sanguineous, (2) serous, (3) mucopurulent, or (4) purulent.

1. *Sanguineous Discharge.* Rupture of the tympanic membrane occurs from concussion either by a loud noise or from a blow on the ear, as in boxing or in diving if the side of the head hits the water; bleeding results and the tear in the tympanum may be seen on direct examination.

2. *Serous Discharge.*—In cases of very acute otitis media the fluid that escapes on rupture or incision of the drum is serosanguineous at first, becoming purulent in two or three days. In some cases, however, notably those due to influenza or to hemolytic streptococci, the discharge may remain serous for several days.

3. *Mucopurulent Discharge.*—This is often seen in cases of chronic otitis media in children in whom the Eustachian tube is comparatively short and wide, but it is not easy to differentiate between mucopurulent and purulent discharge, which is dealt with next.

4. *Purulent Discharge.* The discharge of pus from the ear when examination has shown the canal of the meatus itself to be normal always indicates perforation of the tympanic membrane in consequence of suppuration in the middle ear. When it is the result of *acute otitis media* the discharge ought to diminish in amount in a few days and cease at the end of three weeks; if it does not, suspicion of *mastoiditis* arises, and if there is the slightest mastoid tenderness the suspicion becomes certainty.

Chronic purulent discharge is the result of neglected acute otitis media; it indicates either the presence of some infective focus at the pharyngeal end of the Eustachian tube, e.g., adenoids or tonsils or nasal sinus suppuration, and it will cease on removal of that focus; or that the disease in the tympanum has spread to the bone and is not draining satisfactorily; this is specially so if the disease spreads to the attic.

The position of the perforation gives some indication of the direction in which the disease has spread; perforation of Shrapnell's membrane indicates attic suppuration, a posterior marginal perforation suggests that disease has attacked the mastoid antrum. The pus of chronic otitis media always has an unpleasant odour due to mixed infection, and in some cases the odour is very foul, which is indicative of the presence of cholesteatoma, a material formed by the ingrowth into the attic or antrum of surface epithelium having the power to erode bone. Should the presence of cholesteatoma be diagnosed operation is essential.

Chronic middle-ear suppuration often gives rise to the formation of granulations, and these present themselves in the meatus in the form of little polypi: these polypi may become so large as to fill the meatus entirely, and they bleed.

Tuberculous otitis media is not very uncommon in infants, and is characterized by a purulent otorrhoea, enlargement of the lymphatic glands round the ear, and sometimes by facial paralysis: tubercle bacilli may be detected in the discharge.

Very occasionally a *cerebral or cerebellar abscess* may drain out through the tympanum; the profuse discharge together with the grave antecedent symptoms will assist one in coming to a diagnosis.

W. M. Mollison.

OXALURIA. This term is generally used to include any condition under which crystals of calcium oxalate are to be found on microscopical examination of the urine. They occur in two forms, of which the most characteristic and common is the 'envelope' crystal really a regular octahedron (*Fig. 431*): when crystallization has occurred imperfectly a spheroidal form with a central constriction like that of a 'dumb-bell' may be seen occasionally. Either form is transparent, highly refractile, and usually colourless. If the precipitate is sufficiently abundant to be visible to the naked eye it is pure white: it often comes down after more or less mucus has already gone to the bottom of the specimen glass, so that a dense white layer is seen lying on the top of a less white flocculent mass: this appearance is described as the 'powdered wig'.

The crystals are soluble in any mineral acid, but they are insoluble in water or ordinary acetic acid solution. They may be found in any urine, whether acid or alkaline, but are commonest in acid urines. They may be in the urine when it is voided: more often they form as the urine stands in the specimen glass, and if a slide is prepared from the centrifugized deposit of a urine and allowed to stand for a while before it is examined under the microscope, numbers of very minute calcium oxalate crystals may appear even when none are to be found in a similar specimen examined at once.

The deposition of calcium oxalate is not necessarily pathological: indeed, upwards of 20 mgrm. are excreted in the urine daily, even 35 mgrm. not being beyond the normal limit. So long as the oxalic acid is combined to form soluble salts such as those of sodium or potassium no envelope crystals appear, but it is common for the proportion of oxalic to other acids on the one hand, and of calcium to other bases upon the other, to be such that insoluble oxalate of lime is formed and precipitated, either in the urinary passages or after the specimen has been voided.

Certain patients presenting symptoms of gastric or intestinal indigestion have a curious tendency to suffer from alternating oxaluria and phosphaturia: in their dietetic efforts to obtain comfort they cause marked variations in the reaction of their urine: at one time it is markedly acid and oxalates are precipitated, at another it is alkaline and an abundant deposit of phosphates forms. No special significance attaches to this alternation.

Circumstances which cause an absolute increase in the amount of oxalic acid excreted will naturally increase the tendency to visible oxaluria. The best-known exogenous sources of oxalic acid are certain vegetable products, of which the following in particular may be mentioned: tea, cocoa, rhubarb, spinach, gooseberries, figs, coffee, chicory, chocolate, peas, beans, beetroot, artichokes, tomatoes, and beer. It is probable, however, that there is also an endogenous source for oxalate of lime, for even a starving person still excretes oxalates in his urine. The source of these is still obscure, but it is held by many that uric acid, creatinin, and possibly other allied substances, may be a source of oxalate. The fact that uric acid crystals and those of oxalate of lime are to be seen not infrequently, either together, or alternating with one another on different days, would seem to favour this view,

Fig. 431. Calcium oxalate crystals.

and gouty persons are perhaps more liable than others to oxaluria. Calcium oxalate crystals may be found in the urine at any age, however, from infancy onwards.

In great part, oxaluria is physiological and dietetic; nevertheless there is a decided tendency nowadays to revert to the older view that when a patient's metabolism is such as to cause a constant deposition of calcium oxalate crystals in the urine it is also apt to lead to a group of symptoms of which nervous dyspepsia, neurasthenia, and even hypochondriasis are the chief. The discovery of calcium oxalate crystals in the urine of such patients therefore might be of assistance in determining the nature of the dietetic and other treatment that should be adopted for the cure of the other general symptoms.

There are at least three other ways in which the knowledge of the existence of oxaluria may be important:—

1. Concerns patients who present symptoms that may be due to renal or vesical calculus. Microscopical examination of the centrifugalized urinary deposits in such a case may serve to detect not only pus cells and red blood-discs, but also calcium oxalate crystals that, instead of being all separate from one another, as is the rule in a dietetic or neurasthenic case, are obviously agglomerated into minute calculi; if there are clinical symptoms of stone the discovery of microscopic aggregations of crystals is highly suggestive of there being a larger calculus present somewhere in the urinary system.

2. If oxalate crystals are deposited in numbers in the urine whilst it is still in the bladder irritability of the latter is apt to follow, with a tendency to undue frequency of micturition: such oxaluria is not infrequently the cause of nocturnal enuresis.

3. The same irritation by oxaluria that may produce nocturnal enuresis in girls and boys may lead to the urine of adults containing excess of nucleo-protein, and, in the male, numbers of spermatozoa. There may be no symptoms whatever, and in that case the only importance of the condition lies in the fact that the nucleo-protein may be mistaken for albumin: for if the boiling test is applied to a specimen containing nucleo-protein in excess a cloud of phosphates may come down, and then when acetic acid is added to dissolve up this cloud a residual haze may remain because the acetic acid, at the same time that it dissolves the phosphates, precipitates the nucleo-protein. This source of fallacy may be obviated in either of two ways: the haze of nucleo-protein will clear up on addition of a drop of nitric acid, whereas a similar haze due to albumin will remain: to make quite certain, three test-tubes may be used: into the first put urine without boiling; into the second, urine plus acetic acid without boiling; and into the third, urine plus acetic acid, the mixture being thoroughly boiled. If the haze is due to a nucleo-protein only it will be equally marked in the second and third tubes, whereas if there is albumin as well, the haze in tube three will be denser than that in tube two.

Just as oxaluria may lead to nocturnal enuresis in adolescents, so in a few adult males it has been regarded as a factor in the causation of excessive nocturnal emissions or spermatorrhœa.

Herbert French.

AIN, ABDOMINAL (General).—Most abdominal pain is local, e.g., that due to a gall or biliary stone or to appendicular colic.

Acute General Peritonitis.—This condition is the most serious cause of general abdominal pain. If the peritonitis be perforative, at first the pain is local at the seat of perforation, and the abdomen is retracted: but soon, whether the peritonitis is or is not perforative, the abdomen becomes distended from paralysis of the bowel, and the pain becomes general. Increase in the rate of the pulse, rigidity, and immobility of the abdominal wall on breathing are most important signs for diagnosis. Quickly the pulse becomes more rapid and wiry, the patient looks ill, the temperature is raised a little, the bowels are constipated, and there is some nausea, perhaps vomiting. In cases of doubt it is a good plan to count the pulse-rate at intervals of ten minutes: a progressive rise in the successive pulse-rates often points to the need for urgent laparotomy. There may be a rapidly progressive leucocytosis. It is often said that the drawing up of the knees on to the abdomen is of importance: sometimes it is very striking, but in many patients with acute general peritonitis the legs are not drawn up, and they may be drawn up in other conditions. The early diagnosis of acute general peritonitis is of the utmost importance. It has been estimated that in many cases each hour's delay in opening the abdomen means that the chances of death are increased 5 per cent. Morphia should never be given when

it is thought there is even a remote possibility that any illness is acute general peritonitis, for it makes the subsequent diagnosis so difficult. The onset of *pneumonia* is sometimes announced by an abdominal pain so acute that the patient is thought to have acute general peritonitis: the relatively rapid respiration-rate may point to the lesion being in the chest, but in some of these cases it is only by anxious watching that one can decide whether the disease is primarily thoracic or abdominal. Sometimes it is both—for instance, in pneumococcal septicæmia.

Chronic General Peritonitis. This usually causes a dull feeling of heaviness rather than a general acute pain. The chief points to be observed in arriving at a diagnosis are the chronicity of the trouble, the presence of fluid in the peritoneal cavity, and the fact that masses of thickened peritoneum can often be felt. The most usual is the puckered, thickened omentum, forming a tumour lying transversely at the middle of the abdomen; sometimes other lumps can also be felt. It must not be forgotten that an infiltration of the stomach with new growth will give rise to a tumour lying transversely across the abdomen, and so may a diseased colon. The presence of these peritoneal thickenings often gives the abdomen a dough-like feel. The commonest cause of chronic peritonitis is tubercle. Often there is no discoverable tubercle elsewhere to help us to a diagnosis, but the hectic, irregular temperature may be a guide. As the fluid increases, the umbilicus becomes flattened out (see ASCITES, p. 59), and in tuberculous peritonitis sometimes red.

Intestinal Colic. This is due to many causes which lead to painful contraction of the intestinal muscles. The pain is always paroxysmal and usually recurrent, so that a severe attack consists of frequently recurring paroxysms. There are all degrees, from quite a slight pain to one that causes the patient to shriek and break out into a cold sweat. The temperature is usually normal, but is occasionally slightly raised. The pulse is usually of normal rate unless the temperature be raised. The abdomen is generally distended, and in a bad case peristaltic movements of the coils of intestine may be seen. Often the abdominal muscles are reflexly contracted and rigid. The pain may come on without warning, or may be accompanied by nausea, eructations, and borborygmi. It is usually felt at the umbilicus, from which region in a severe case it spreads over the whole abdomen. The patient tosses about in the severity of it, and finally selects a position in which he can bring pressure to bear on the abdominal wall: in peritonitis this, so far from relieving the abdominal pain, increases it. Intestinal colic is usually brought on by eating some indigestible article of food, so the history will help us; but it may be due to obstruction; or to the effects of gastro-intestinal irritants, or poisonous drugs, such as arsenic, antimony, or lead; or to the excessive use of purgatives, such as calomel, colocynth, aloes, jalap, and magnesium sulphate. In children, intestinal colic is recognized by their cries, restlessness, and the drawing up of the legs.

Acute or Subacute Intestinal Obstruction is a common cause of general abdominal pain, and requires most careful diagnosis (see VOMITING, p. 927).

Lead Colic. This is diagnosed by the symptoms of colic, as given above, by the history and occupation, and by the presence of other signs of lead poisoning (p. 45), of which the most characteristic is a blue line on the gums.

Gastric Crises may cause general abdominal pain, but they will be recognized by the absence of knee-jerks and other signs of tabes dorsalis.

Abdominal Neuralgias. This phrase is applied to severe abdominal pains unassociated with any organic disease. The greatest caution must be exercised, and a diagnosis of abdominal neuralgia must be looked upon with great suspicion, for there is no doubt that such a diagnosis is often wrong, the patient really having organic disease. The pain may be local—e.g., those neuralgias of the kidney which resemble renal calculus—or it may be general; or it may start locally, for instance, over the solar plexus in the epigastrium, and radiate thence so widely as to be complained of “all over the abdomen”; the less local the pain the more likely is it to have a neuralgic basis if no organic lesion becomes apparent on routine examination. Disease of the spine must be excluded carefully. Often these patients have neuralgia elsewhere. The cases last a long while; they are commoner in women than men. In a few, opening the abdomen has shown that the small intestine or colon is spasmodically contracted (*enterospasm*), and, indeed, it may be felt through the abdominal wall as a swelling like a thick cord. These patients are often given morphia, but this should not be done. It is not infrequent to find that severe abdominal

pain is apparently due to the administration of morphia, for the pain ceases when the drug is withheld. I have seen two such cases recently.

General Visceroptosis often causes a general dull, dragging abdominal pain. It can easily be diagnosed by feeling the displaced liver or kidney, by looking at the abdominal

Fig. 432.—Skiagram to show the normal appearance of the rectum, colon, and cecum after injection of the bowel with a bismuth enema. Note that food has passed the ileocecal valve and entered the small bowel. Male, age 14. (By Dr. C. Thurstan Holland.)

outline seen from the side when the patient stands up (see *Fig. 146*, p. 165; see also *CONSTIPATION*, p. 158), and by observing the displaced stomach or intestines by the X rays after the administration of bismuth. (Compare *Fig. 432* with *Fig. 433*.) *W. Hale White.*

PAIN IN THE ANKLE.—(See *JOINTS, AFFECTIONS OF THE*, p. 423.)

PAIN IN THE ARM.—(See *PAIN IN THE EXTREMITY, UPPER*, p. 543.)

PAIN IN THE BACK.—From occiput to anus, a pain referred to the spinal axis is a frequent complaint, and the diagnosis of its cause is often a troublesome problem. We begin with the broad generalization that a pain in any area must be due to irritation, either of the trunk or the terminals of the sensory nerves supplying the spot, or, it may be, of a nerve which is in immediate anastomosis with that to the painful area. Pain referred to any one spot and due to central (cerebral) irritation is so rare as not to require mention here (except that arising from gross cerebral trouble, which will be referred to by the patient as *HEADACHE*, p. 369); and applying this principle to the spinal axis, we find that the sensory divisions of the spinal nerves, from the first cervical to the coccygeal, all divide into branches for (*a*) the skin, (*b*) the bones and meninges of the spinal canal, (*c*) the muscles lying on the vertebral column, and (*d*) the viscera contained in the cranium, neck, thorax, abdomen, and pelvis. Consequently, to interpret rightly the meaning of a pain in the back, we must look not only to general conditions affecting the blood (fevers of all sorts are often associated with a general backache as a prominent feature), but to the condition of the organs contained in that spinal segment (or the one immediately above or below it) in which the pain is complained of.

Another very useful generalization is this. We may draw a distinction between a pain complained of spontaneously in a spot not associated with tenderness on firm pressure, and one in which such tenderness is present. In the latter case, the tender spot is located in all probability at or near the seat of the trouble; in the former case it is probable that

the pain is one referred by the brain to the spot, but not really arising there—a 'referred pain', as it is termed; and this is the more likely if we find that the skin over the area is very sensitive to light stimulus, but not more sensitive—perhaps even less so—to a stimulus which is rather rougher, a pressure rather firmer than a light touch. Carrying this to its extreme, we have the paradoxical phenomenon of severe pain being complained of in an area the skin over which is absolutely anæsthetic; this indicates a complete lesion of the trunk of the nerve concerned.

Coming now to the practical diagnosis of a pain in the back, we can pretty easily and accurately eliminate those cases owning a pyrexial origin by observing that the patient not only complains of a pain in the back but looks acutely ill; if he does so, take his temperature, and if this is found to be raised above 100° F., we may be sure that we have to deal with a zymotic disease at its onset, or perhaps it may be with a meningitis or a myelitis or even acute rheumatism, and in all of these the pain in the back is only an obtrusive symptom, to which will very soon be added some of the signs distinctive of the disease.

Often, however, we have to deal with cases in which the patient, except for the pain in the back, is comparatively well, and he is concerned to know what it means. Two or three questions immediately arise in such a case, the answers to which will throw light on the nature of the trouble. The first thing is to ask him to locate the pain; the next to inquire how did it arise, i.e., did it come suddenly after a blow? after some unusual exertion? after some unintentional movement, say of the head and neck, or a slip off a pavement? And then again, how long has he had it, and has he ever had a similar pain before? Again we proceed to ask, is it constant or intermittent? If the latter, what action on the patient's part will cause it to return, or what position will ease it when it is present?

It is but seldom that we have not by these questions arrived at a provisional diagnosis in our own minds, but we must never omit to make a careful physical examination for points which will corroborate or correct this diagnosis.

Inspection may reveal skin conditions, such as a patch of herpes, which may be either the real cause or an outward manifestation of a cord or bone lesion; swellings or redness may be apparent, or undue prominence of a spinal process; bruises or purpura may be seen, or a pulsating tumour proving aneurysm; glands may be visible in the posterior triangle of the neck. It will also reveal any trace of lateral curvature, a frequent source of backache in young people.

Palpation may reveal great tenderness on pressure, either of muscles or bone; it may show fluctuation (remember that this fluctuation must be vertical, not lateral, to be reliable); it may prove the absence of tenderness, and may also show hyperæsthesia of the skin, suggestive of pain referred from a viscus. A very useful hint is frequently derived from the observation of the results of palpation; sometimes these can better be seen when a special stimulus such as an electric current or persistent rubbing is applied to the skin; thus it may be found that over one small area a blush is raised more easily, or is more persistent, than elsewhere; this is strong evidence pointing to visceral disease as the cause of the pain; it is due to, and proves disorganization of, the sympathetic nerve distributed to the viscus. This method will also reveal hyperæsthesia or anæsthesia if testing be conducted with a light touch and a pin.

The next step is to apply tests for disease of the bony walls of the canal; tap each spinal process in turn with a percussion hammer, and note whether pain is elicited at any spot; jar the heels alternately with the leg held rigid from the hip; letting the patient come down on the heels himself is more risky and less satisfactory; also test for pain on resisted movements of the limbs or trunk. We may then find if pain is aroused by movements of any kind—flexion, extension, and rotation.

Lastly, with the patient lying on his back, a careful examination must be made from the front in the ordinary way for evidence of any visceral disease, or of growth of any kind. If the cause of the trouble should still remain obscure, or perhaps in any case for future reference, two or three X-ray photographs of the painful area will be taken.

We may now consider the reverse order of procedure, and ask what are the local diseases associated with pain in the back, and what are their distinguishing points. We may enumerate these according to the structures involved, thus:—

Skin.—Ulcers, herpes, etc.: obvious on inspection.

Muscles.—Abscess, trauma, inflammation: so-called rheumatism, stiff neck, lumbago, etc.; simple debility: overwork.

Joints.—Rheumatism; implication in caries or in rheumatoid arthritis, etc.

Bones.—Caries, aneurysm, growths eroding; trauma.

Meninges.—Inflammation; growth; syphilis.

Cord itself.—Tumour; inflammation; trauma.

Viscera in front.—Aneurysm; gastric or duodenal ulcer; dyspepsia; gall-stones; uterine or ovarian trouble; appendix; rectum; bladder and vesiculae seminales; kidneys.

It would be impossible within the limits of this article to give a complete differential diagnosis of all the above, but the procedures of investigation which we have already noticed will almost certainly enable us to come to some conclusion, and it remains here only to indicate a few of the more special points in differential indications, and a few of the commoner mistakes.

Lumbago v. Tumours.—If a patient complains of 'lumbago' of some standing, it is essential to test the nervous system, the knee-jerks and other leg reflexes, and to contrast them on the two sides; to look for wasting of muscles, especially on one side, to investigate the power of the muscles in walking and in simpler movements; to examine the pelvic organs and the abdomen for growths of any kind. Only when all these points yield negative results can we permit ourselves to think that it is simple lumbago. Lumbago is almost always on both sides; a tumour most frequently gives one-sided symptoms first, though they may spread to the other side later. The pain of lumbago is increased when the lumbar muscles are put into action, and these muscles are tender on deep palpation. Rectal examination should never be omitted, and in suitable cases vaginal examination should be made also.

Aneurysm in Thorax v. Indigestion, etc.—It cannot be said that this is a common mistake, but it is a very serious one. The difficulty is that an aneurysm is extremely hard to recognize when it arises from the descending aorta; bruits are usually absent, and it is perhaps only when a pulsating tumour in the back appears that the diagnosis is made. The severity, the dull, aching character, and the persistence of the pain are the main features that may help to suggest such a serious cause. The patient should be investigated by the X rays.

Occipital Headaches v. Caries of Spine.—Owing to the frequency with which delicate patients, particularly women and young subjects, complain of pain in the neck, it is well to draw special attention to this locality, though diagnosis is fairly easy. The occipital headache due to a tumour is unmistakable by its severity, and the almost invariable association of vomiting and optic neuritis. The dull, constant, wearing pain of caries, worse on any slight jar, and the fixed position in which the patient holds the head, are sufficient to arouse suspicion; the X rays will almost certainly clear up the diagnosis. A stiff neck is acute in its onset, and generally preceded by a definite history of sitting in draught. A 'crick in the neck', possibly the equivalent for the rupture of a few ligamentous or muscular fibres, can be recognized by its sudden occurrence in the midst of health with no history of previous pain; occipital pain is not infrequently complained of by patients suffering from disease of the sphenoid bone or from sphenoidal sinusitis.

Debility in Youth or Lateral Curvature v. Caries.—The shapes of the curves are usually sufficient; but care must be taken to examine the integrity of the bones by the tests given above, and one must not be satisfied until all the bone tests have been tried and found negative. Local rigidity over the painful area, best tested by making the patient stoop and rise again, whilst the physician feels the spine with the flat of the hand, is strong evidence, if persistent, of caries.

Pelvic Organ Trouble v. Lumbago. This mistake is of course more frequent in women than in men. The only rule to be laid down is always to think of these organs when a woman complains of 'lumbago' or 'backache', and to inquire carefully into the history of confinements and menstruation, and to make a thorough examination. More mistakes are made in the diagnosis of a pain in the back from want of thought and from carelessness in examination than from any inherent difficulties in the diagnosis, at any rate in so far as the more serious causes are concerned.

E. Farquhar Buzzard.

PAIN, BEARING-DOWN. This form of pain is very frequent in diseases of women, and is an associate of many pelvic conditions. It is impossible in many instances to dissociate it from chronic aching pain; but it is not every chronic pain which has the bearing-down character. It is usually the result of impaction of some pelvic structure, and owes its character more particularly to pressure on the rectum, and sometimes on the bladder. Displacement of pelvic organs, or even simple congestion of them, will sometimes produce it. Its source is not always strictly gynaecological, as it may be the result of rectal disease, such as cancer, ulcer, or hemorrhoids. It is thus closely associated with rectal tenesmus. The commonest cause is, perhaps, backward displacement of the uterus, and it is most marked in retroversion of the pregnant uterus, especially if impaction of the organ occurs. Impaction of a pelvic tumour may produce it, uterine fibroids, ovarian tumours, and pelvic hæmatocele being the chief swellings which give rise to it. These produce pain of a different character in addition, due to pressure on nerves; but the bearing-down character is more particularly referred to the rectum, hence it is commonly believed to have some relation to pressure on the rectum. A pelvic abscess of peritoneal origin is an unusual impacted swelling, which gives rise to very severe bearing-down pain — impacted, because it is bound down by peritoneal adhesions, and exercising pressure because of the tension in it. The bearing-down character becomes most marked if the abscess involves the rectal wall, as it so frequently does, causing a flow of mucus and much irritation of the rectum.

The differential diagnosis of the causes of this type of pain can be made only after a complete pelvic examination by abdominal palpation, and bimanual examination by the vaginal and by the rectal touch. Further, it may be necessary to examine the bladder by the cystoscope, or the rectum by finger or sigmoidoscope. The differential diagnosis of the pelvic disorders mentioned is discussed under SWELLING, PELVIC (p. 840). *T. G. Stevens.*

PAIN IN THE BREAST. When pain in one breast is the chief symptom that a patient complains of, the first and most important step in arriving at a diagnosis is to make a thorough examination of both breasts by inspection and palpation with a view to detecting any abnormality at all which might suggest an early carcinoma. The methods of such examinations are described on page 837. Unfortunately pain does not occur early in cases of carcinoma of the breast, and by the time it is pronounced there is generally an obvious stony-hard tumour.

Other causes of pain in the breast are:

Pregnancy	Galaetoele	The effects of the pressure of the tops of stays; or the pressure of a fountain pen worn in the dress
Menstruation	Epithelioma of the nipple	
The onset of puberty	Tuberculous disease of the breast	Indigestion
Cracked nipple	Mastodynia	
Inflammation of the nipple	The after-effects of a blow or injury	Heart disease
Cyst of the breast		Imagination.
Submammary abscess		
Mastitis, acute, subacute, or chronic		

The diagnosis between some of these various conditions is discussed under the heading of SWELLING, MAMMARY, p. 837.

Pains in the breast due to intra-uterine or to ectopic *pregnancy* will generally be bilateral and associated with the other signs of pregnancy: in unexpected cases suspicion may be aroused by the dark brown colour of nipples which should be pink, and by the broad secondary areola and swollen Montgomery's glands developing around it.

The pains in the breast that are associated sometimes with *menstruation* are also bilateral, and their cause may be indicated by their development synchronously with the first menstruation or their periodic recurrence at each menstrual period in an older person.

The chief difficulty in the diagnosis occurs in patients whose breasts may be irritated perhaps by a hard upper border to their stays, or who may have had a breast pain caused by some forgotten injury, but who, perhaps from the occurrence of other cases in their own family or amongst their friends, become terrified by the thought that the sensation which they have is an indication of incipient cancer of the breast. Once this fear has started the pain may assume larger and larger proportions without any existing cause at all:

whether to label such a pain in the breast hysterical or a neuralgia or something else is difficult to decide, but the function of the physician or surgeon will be to examine the breast with extreme care, not only once but at intervals, in order to convince himself, and subsequently the patient, that no tumour at all is forming there. He may very likely be in some doubt himself for a while, but in the absence of any trace of even a minute nodule he will be justified in waiting for re-examination at intervals: should the slightest nodule become palpable he will generally be justified in advising its removal for microscopical examination even though he has little doubt that it is non-cancerous: but if week by week nothing abnormal whatever can be found in the breast the diagnosis of functional breast pain will be established: and when the patient's mind is set at ease by the absence of any further developments, the pain, previously to her mind severe, will often disappear.

Herbert French.

PAIN IN THE CHEST is common in all sorts of disorders: in the case of highly intelligent persons help in diagnosing the cause of such pains can be obtained by inquiring into their individual characters, but more assistance is furnished by investigating the circumstances in which the pain is chiefly felt, and the conditions that ease or aggravate it. Thus chest-pains due to disease of the heart will be increased by anything that makes the heart beat more rapidly: those due to lung disease by anything causing the patient to breathe faster or cough: those caused by disorders of the stomach will generally be aggravated by or soon after taking food. For pains in the back wall of the chest, see **PAIN IN THE BACK** (p. 526) and **PAIN, INTERSCAPULAR** (p. 565). For clinical purposes, pains in the chest may be classified according to their pathology, and the nature and situation of the disorders to which they are due.

1. Pains due to Diseases of the Tissues composing the Thoracic Walls: the pain is in most cases a direct pain, associated with local tenderness:

Inflammation of the skin and subcutaneous tissues	Stitch
Mastitis	Neuralgia
Adiposis dolorosa	Mastodynia
Neurofibromatosis	Herpes zoster
Myalgia	Pressure on nerves
Pleurodynia	Disease of the bones of the chest
	Slipping rib.

2. Diseases of the Thoracic or Abdominal Viscera: the pain is in most cases a referred pain, though there may be local tenderness:—

Pleurisy	Aneurysm
Empyema	Dissecting aneurysm
Pneumothorax	Mediastinal new growth
Pneumonia	Mediastinitis
Pulmonary embolism	Œsophageal obstruction
Heart disease: Valvular disease, aortitis,	Diseases of the spine
angina pectoris, true and false	Subphrenic abscess
Pericarditis	Hepatic abscess.

1. Diseases of the Thoracic Wall. Pain in the chest due to *inflammation of its superficial tissues* should not be hard to diagnose. The pain will be confined to the inflamed parts and their immediate neighbourhood, and the other three cardinal signs of inflammation—heat, redness, swelling—will not be absent. In most cases a superficial wound or abrasion will be found: in others, the inflammation will have spread to the surface from some deep-seated lesion, caries of a rib, for example, or an empyema or hepatic abscess, or a metastatic abscess arising in the course of pyæmia. The diagnosis must be made on general lines in these unusual cases. *Mastitis* or *mammary carcinoma* will be diagnosed by palpation. The inflammatory phenomena of *herpes zoster* are considered below.

The very rare condition known as *adiposis dolorosa*, or *Dercum's disease* (p. 509), is characterized by symmetrical and painful deposits of fat about the body and limbs. It occurs mainly in middle-aged women of full habit, though males are not exempt: chronic alcoholism is its usual precursor. *Neurofibromatosis* is characterized by the growth of multiple benign false neuromata on the nerves, which give rise to pain: but they are not tender on pressure, and so contrast with the single false neuromata, which equally give rise to pain over the area of distribution of the nerves on which they are situated.

When pain is felt in the intercostal or other muscles about the chest, and can be referred to nothing more definite than 'muscular rheumatism', the condition is alluded to as one of *myalgia* or *pleurodynia*. Tenderness of the affected muscles is the only physical sign present, and it is important that graver mischief, such as pleurisy, pneumonia, or aortic aneurysm, should be excluded before the diagnosis of pleurodynia is made. The sudden pain in the side familiar to untrained athletes as *stitch* comes on after sudden exertion, and is in all probability due to overstrain of the fibres of part of an intercostal muscle. All these muscular pains are relieved by rest or pressure, and aggravated by exertion.

Pains in the chest may be due to *neuralgia*, a term which is theoretically applied to pain felt in a nerve that shows no evidence of active or old disease. Practically, however, neuralgia is the name also given to nerve-pains that follow organic disease both in the nerve itself (herpes, neuritis, etc.) and in other parts of the body (gout, tabes, etc.). In *intercostal neuralgia* the pain is felt along the course and distribution of one or more of the intercostal nerves. There is marked tenderness on pressure in the affected intercostal space, with three points of maximum tenderness corresponding to the posterior primary, lateral cutaneous, and anterior cutaneous branches of the nerve, given off near the vertebral spines, the mid-axillary region, and the costosternal articulations. The pain is increased by movement or breathing. Unilateral intercostal neuralgia frequently follows herpes, and must be distinguished carefully from pains that may be felt in organic disease, such as tabes, aneurysm or mediastinal tumour, and vertebral caries, in which the intercostal nerve is directly or indirectly involved. In *phrenic* or *diaphragmatic neuralgia*—a rare condition—the pain is felt in the lower part of the thorax along the line of insertion of the diaphragm, which may be tender on pressure: coughing and breathing are acutely painful, but there will be no physical signs of disease except the tenderness on pressure. The diagnosis must be made from diaphragmatic pleurisy or peritonitis, acute hepatic or splenic disorders, and spinal caries, on general lines. *Mastodynia*, mammary neuralgia, or the 'irritable breast' of Astley Cooper, occurs in women during pregnancy or lactation, or in connection with pelvic disease. The pain is constant, with paroxysmal exacerbations, and its severity may lead to the fear of cancer. Local changes—redness, swelling, tenderness—may be found about the breast and nipple.

Pains in the chest are habitually felt in *herpes zoster* of the intercostal nerves, sometimes before, always during, and often after the attack: the third, fourth, and fifth intercostals are those most often involved. Groups of vesicles arise over the area of distribution of the affected nerve, filled with serum and implanted on an inflamed base: they are most marked about the exits of the posterior primary, lateral cutaneous, and anterior cutaneous branches. The axillary glands become enlarged if the herpes is above the seventh dorsal nerve, the inguinal if it is below it. In about a week the eruption scabs over: if the spots become septic, small whitish scars remain as permanent evidence of the attack. The diagnosis is obvious in cases presenting the eruption or its scars, but may be difficult until the herpetic vesicles have appeared. It is especially in older patients that severe neuralgic pains are likely to remain for months or years as a legacy from herpes.

Pains in the chest will be felt whenever there is *pressure on an intercostal nerve*: in many cases such pressure is bilateral, when the patient will complain of girdle-pains. *Injury* or *fracture* of the spinal column may involve the posterior nerve-roots or the intercostal nerves, either at once by the pressure of fractured bone or of effused blood, or later by the pressure of callus: *abscess*, *aneurysm*, or primary or secondary *new growth*, may press on a nerve and give rise to severe pain in its area of distribution. In most cases there will be other physical signs or symptoms to point to the diagnosis: but where there are none, and the pain is due, perhaps, to a minute carcinoma in the spinal canal, or to a small thoracic aneurysm that strikes backwards and presses on an intercostal nerve, there is no little danger lest the patient be treated for functional disorder or malingering. The pains are very severe, and persist for months in spite of treatment, while the patient is likely to lose health, weight, and strength. It is true that these phenomena may also be observed in functional cases: but the diagnosis of functional disease or neuralgia should not be made until the most careful physical examination, including the use of the X rays, has excluded organic disease of all sorts.

Chest-pains may result from local *injury* or from *inflammation of the bones* of the

chest-coecal infections, tuberculosis, hydatid disease, etc. or of the *joints* connected with these bones.

2. Diseases of the Viscera. Pain in the chest is extremely common in the various diseases of the thoracic viscera, inflammatory or otherwise. In *acute pleurisy* the onset is often insidious, and the pain is felt most acutely in the mammary or axillary region, being made worse on breathing deeply or coughing. The pain is stitch-like, lancinating, described as resembling 'a knife', 'stabbing', 'tearing'; it is relieved by anything that assists in immobilizing the affected side. The intercostal spaces are tender to pressure in pleurisy, just as they are in intercostal myalgia. The diagnosis turns on the discovery of other physical signs of pleurisy, particularly of pleural friction-sounds. In *diaphragmatic pleurisy* the pain is felt in two chief sites: one near the costal margin, corresponding to the attachment of the diaphragm; the other about the crest of the shoulder, corresponding to the cutaneous distribution of the fourth cervical nerve: this is a referred pain, due to afferent stimuli coming up the phrenic nerve to the spinal centre of the fourth cervical nerve. The pleuritic friction-sounds often fail to make themselves heard in diaphragmatic pleurisy, and the diagnosis of intra-abdominal disease (cholecystitis, appendicitis, peritonitis) has often been made and acted upon in such instances. The pain in *empyema* is much like that of pleurisy: it should be noted that the appearance of a pleural effusion, whether serous or purulent, often coincides with a diminution in the amount of pain felt, because the two inflamed pleural surfaces become separated by the fluid and cease to be rubbed together by the respiratory movements. *Chronic pleurisy* and old pleural adhesions give rise to much of the chronic pain in the chest and shoulders and root of the neck that occurs from time to time in patients with pulmonary tuberculosis. Pain and tightness in the chest are common in *bronchitis*, with or without *emphysema*: here the diagnosis will not be difficult if pleurisy can be excluded, and much of the pain is probably due to overstrain of the intercostal muscles and diaphragm in coughing.

In *pneumothorax*, about half the cases show an acute onset, with the sense of something tearing or giving way in the chest, and sudden very severe pain in the side, aggravated by breathing. In addition the patient exhibits dyspnoea, prostration, cyanosis, and rapid and feeble action of the heart. The onset in the other half of the cases is insidious, and the condition subacute or chronic, with comparatively little complaint of pain. The diagnosis, if not made from the history, should be manifest on consideration of the physical signs. The affected side of the chest moves very little on respiration, and is increased in measurement; vocal fremitus is absent; the note on percussion is usually tympanitic, in rare cases dull; and the voice- and breath-sounds are absent on auscultation. If the pneumothorax is at all extensive the heart will be displaced considerably towards the sound side. Examination with the X rays will show that the diaphragm is immobile on

the affected side, and the air-containing pleural cavity extremely translucent (*Fig. 511*, 8); the lung forms a shrunken and opaque mass near the middle line and against the spinal column. After a few days more or less evidence of pleural effusion at the base of the pleural cavity will usually be found in the lowest part of the pneumothorax cavity, and pleural succussion may be heard if the patient is shaken to and fro whilst the chest is auscultated.

In *pneumonia*, chest-pain is extremely common, and is due to pleurisy. If the physical signs characteristic of pneumonia delay their appearance, as is sometimes the case, and if the pleural friction escapes detection, the diagnosis of some relatively harmless condition such as pleurodynia or intercostal neuralgia may incautiously be made. This mistake is not likely to occur if due attention be paid to the patient's temperature, aspect, pulse, and pulse-respiration ratio.

Pain in the chest is common in *acute pericarditis*, and is referred to the precordia generally, or to the lower part of the sternum. In many cases no complaint of pain is made; in a few instances the pain is exceedingly severe, resembling that of angina pectoris. The diagnosis will turn on the discovery of other signs or symptoms of pericarditis, particularly of pericardial friction-sounds; the patient is often pale and anxious-looking, and very short of breath. The friction-sounds often remain unchanged when a dry pericarditis has been converted into a wet one by the effusion of fluid: they are characteristically a superficial shuffling, grating, rubbing, or creaking, often not

synchronous with either systole or diastole : sometimes altered by pressure with the stethoscope or by changing the patient's position : frequently varying from day to day : not conducted well in any direction beyond the precordia, being heard within an area that often does not correspond with the areas of audition of valvular murmurs : sometimes associated with a typical canter rhythm of the heart. These characters should suffice to distinguish pericardial friction-sounds from the murmurs of valvular disease : but it may be very difficult in certain cases to distinguish pericardial from *pleuropericardial friction-sounds* that is to say, friction-sounds generated in pleurisy by the heart's movements. If there is pleurisy over the thin anterior edge of the left lung, the beating of the heart will readily give rise to friction-sounds that have a cardiac and not a respiratory rhythm, but are due to pleurisy and not to pericarditis. Pain in the chest will be felt in either case : the two may generally be discriminated by the influence of deep inspiration and expiration on the friction-sound. In pericarditis, expiration will strengthen and inspiration will weaken (but not abolish) the friction-sounds. Pleuropericardial friction will in all probability be altered profoundly by respiration, being much increased in one phase (whether inspiration or expiration), much diminished, or lost, in another.

Pain in the chest is common in cases of *heart disease*, taking in general two forms : (1) Precordial pain : and (2) PALPITATION (p. 594). There is nothing characteristic about the precordial pain felt in heart disease, except the fact that it is brought on most often by exertion or excitement. Very similar pain may be experienced by patients with sound hearts who are suffering from *flatulent dyspepsia* : here the pain is usually felt after meals, but may be brought on by exertion if the latter is made soon after food has been taken. The diagnosis must be based on the general signs and symptoms exhibited by the cardiac patient. In *aortic incompetence*, the precordial pain is sometimes exceptionally severe, taking the character of angina pectoris, and radiating down the left arm or through to the back. The sensory nerves of the heart are connected with the spinal cord from the first to the eighth dorsal nerve roots : the first and also the most painful impressions are usually received at the second dorsal roots, which are described as being most central to the paths of pain from the heart. The painful impressions received from the heart at these root-centres are referred to the corresponding areas of cutaneous nerve distribution. Those from the ventricle ascend from the second to the fifth : from the auricle, the fifth to the eighth : from the ascending aorta, the third and fourth cervical and the first to the third dorsal root-centres. These anatomical connections explain the distribution of the pains in the chest and elsewhere felt in diseases of the heart and aorta. Severe pain in the chest, often of anginal character, is felt in acute or chronic *aortitis* occurring in young syphilitic or rheumatic patients, with or without valvular disease : the pain is most marked when the base of the aorta and the coronary orifices are involved.

Pains in the chest, together with mental anguish, are the outstanding features of *true angina pectoris*, and are in most cases brought on by exertion, excitement, or anger. The pain is in the region of the heart, and suggests that the heart has been caught in a vice, so excruciating is it. A sense of impending dissolution, or of a pause in the operations of nature, has been described as added to the physical torture. Radiations of the pains through to the shoulder, down the left arm's inner side to the little and ring fingers (less often down the right arm), up the neck, into the supra-orbital region, are very common. The patient becomes faint and collapsed, pale, and clammy : the pulse changes : flatulence and the passage of abundant pale urine follow the attack, which may last for a few seconds or minutes, or may continue, with varying intensity, for hours. The diagnosis will rest on the extreme severity of the pain, its association with valvular disease or arteriosclerosis, or both, and the fact that the attacks are almost always brought on by exertion or severe emotion. The true must be distinguished from *false angina pectoris*, also called pseudo-angina or vasomotor angina pectoris. This commonly has a neurotic, less often a toxic (tobacco, tea, coffee) basis ; it is less severe, and is never fatal. It is far commoner in women than in men ; often comes on when the patient is at rest, or at night ; may occur at any age, and is not associated with cardiac or vascular disease. Attacks of false angina last for an hour or two. True angina is perhaps ten times commoner in men than in women, and occurs between the ages of forty and sixty as a rule ; false angina is perhaps five times as common in women as in men, and occurs in younger patients. Typical cases of the two conditions will be readily distinguished from one another, but

every gradation is met with, and it may be impossible to refer intermediate cases—for example, patients with severe heart-attacks and valvular or myocardial lesions—with precision to either one class or the other.

Chronic or recurrent pain in the chest is a very variable symptom of *aortic aneurysm*. In some patients a large aneurysm may erode ribs, cartilages, and intercostal spaces, and present itself at the surface of the body without having made itself felt. In others, agonizing pain (true angina pectoris) may be occasioned before an aneurysm at the root of the aorta has grown large enough to produce any physical signs at all: in these the pain is no doubt due to aortitis or mesaortitis for the most part, or to obstruction at the coronary orifices. Speaking generally, the pain of aortic aneurysm may arise in two ways: (1) From changes in the aortic wall, already considered; and (2) From pressure on neighbouring structures, particularly the walls of the chest. Pressure-erosion of the sternum or costal cartilages may be comparatively painless in fortunate cases. Erosion of the vertebral bodies (*Fig. 434*) commonly gives rise to intense and continuous boring

Fig. 434.—skiagram of the thorax taken in the oblique position to show a large aortic aneurysm eroding the 7th, 8th, 9th, and 10th dorsal vertebræ. The upper and lower limits of the aneurysm in the posterior mediastinum are marked by the arrows. The numbers indicate the corresponding dorsal vertebral levels. (*Fig. Dr. W. H. Coddell.*)

pains in the chest that wear the patient out and make life insupportable: girdle-pain may result from pressure on the intercostal nerves (direct pain), and referred pains up the neck or down the inner side of either arm may also be felt. Pressure on the œsophagus may give rise to dysphagia and pain, the pain being increased by swallowing. Compression of the lung may lead to pulmonary collapse and inflammation, when pain from pleurisy will probably be felt. It appears that no particular complaint of pain follows compression of the trachea, bronchi, phrenic or vagus nerves, or heart. An acute and severe pain, on the other hand, may arise should the aortic aneurysm perforate and allow blood to escape into the adjoining parts. Such perforation may take place into the air-passages, œsophagus, large intrathoracic pulmonary or systemic veins, pericardium, heart, pleura, peritoneum, or spinal canal. The appearance of the appropriate physical signs will suggest the diagnosis of such a perforation. If the effused blood is limited in amount, the patient will appear more or less blanched and collapsed: if a great quantity escapes, rapid or sudden death may occur. Particular mention may here be made of the pain due to the formation of a *dissecting aneurysm*. The arteries are acutely sensitive to pain, as may be seen when an artery is ligatured in a conscious patient: the establishment of a dissecting aneurysm

is a terribly painful experience, and is equivalent to an attack of true angina pectoris. If the escape of blood is limited by the walls of the aorta, recovery is likely to occur. The diagnosis of such an incident could only be made on grounds of probability.

Pain in the chest is usually an early symptom of *mediastinal new growth*, and varies in its nature and distribution with the cause and site of its origin. If the growth is in the anterior mediastinum, the pain will be behind the sternum: if in the posterior mediastinum, pressure on or erosion of the vertebræ will set up the severe continuous boring pain referred to above as occurring in aortic aneurysm: if one side of the chest is involved, the pain will be felt in the side, and down the arm if the brachial plexus is pressed upon. It is often of a darting and lancinating character, shooting up into the neck and head, or down into the abdomen. It may be constant, intermittent, or paroxysmal: in some cases it is a discomfort rather than a pain, the complaint being of fullness or tightness in the chest. Other symptoms of mediastinal tumour are, first and foremost, continuous or paroxysmal dyspnoea; evidences of pressure on the air-passages, œsophagus, or nerves: cough, expectoration, hæmoptysis, alterations in the voice or cough; disturbances in the action of the heart, and evidence of venous obstruction. Anæmia or even cancerous cachexia

is not rare. The general diagnosis of mediastinal tumour (including aneurysm) is seldom difficult once pressure-symptoms of any sort have appeared, for these are very rarely caused by other lung conditions associated with pain in the chest, such as bronchitis, bronchiectasis, or pulmonary tuberculosis. But it may be very difficult to decide between aortic aneurysm and mediastinal new growth in certain cases. Aneurysm is commoner in men than in women, and rare in persons who have not had syphilis; the patients commonly give a positive Wassermann reaction; anginal pains and the very severe pain of bone-erosion are commoner in aneurysm than in mediastinal new growth; anemia, cachexia, and irregular pyrexia are in favour of new growth; and so is the discovery of new growth in other parts of the body and of secondarily-infected lymphatic glands. Examination under the X rays will prove of the greatest help (*Figs. 434, 435; and see Fig. 219, p. 260*).

In *acute mediastinitis* and *mediastinal abscess* both of them rare disorders and due to syphilitic, tuberculous, or other infection of the mediastinum pain behind the sternum is commonly the chief complaint, with marked superficial tenderness and a tendency to radiation through into the back or shoulder. Local signs of fullness and inflammation may develop, particularly about the intercostal spaces in front and the episternal notch; and mediastinal crepitations resembling pleural friction have been heard about the sternum.

In *chronic mediastinitis* or *mediastino-pericarditis* another rare condition due to inflammation arising in the mediastinum, or spreading to it from the pericardium, and seen in youth or early adult life chronic pain behind the sternum and a sense of tightness and dragging in the chest may be present. The main symptoms will be cardio-vascular, valvular disease of the heart and adherent pericardium leading to cardiac troubles, and the mediastinitis causing venous obstruction; shortness of breath with sudden and severe attacks of dyspnoea, lividity, anasarca, ascites, and progressive distention of the thoracic veins. New growth will be excluded by the duration of the case. Broadbent's sign may be obvious—systolic retraction of the chest wall below the angle of the left scapula behind synchronous with the heart-beat.

Deep-seated pain within the chest and at the bottom of the sternum may result from disease of the *oesophagus*, being evoked by the act of swallowing. In cicatricial stricture or carcinoma of the tube, pain is less prominent than DYSPHAGIA (p. 240), and progressive emaciation is the rule. In younger and neurotic patients, on the other hand, spasmodic stricture of the oesophagus may give rise to difficulty in swallowing, with much complaint of pain and constriction in the throat and chest. This condition, termed *oesophagismus*, or *cardiospasm*, or *achalasia oesophagi* (*Fig. 208, p. 244*), may be diagnosable only when the passage of bismuth down the oesophagus is watched under the X rays: the patient may be perfectly sensible and apparently free from neurosis, but it is a little more liable to be met with in hysterical young persons and in hypochondriacal old ones; it is not always improved or cured by the passage of a bougie; indeed it may be so troublesome and persistent that nothing short of operative division of the muscular fibres at the cardiac end of the oesophagus will relieve it.

Fig. 435.—Skiagraph of an aneurysm (*A*) of the innominate artery. The projection marked *B* is not aneurysmal, but is the distal part of the aortic arch, often mistaken for an aneurysm. It is sometimes referred to as the aortic 'knuckle'. It shows more prominently than usual in this photograph because it is displaced to the patient's left by the aneurysm of the innominate artery. (*By Dr. W. H. Coldwell.*)

Pain in the chest is met with frequently in diseases of the abdominal viscera, particularly of the stomach. 'Pains round the heart', often accompanied by or productive of PALPITATION (p. 594), are the common basis upon which patients build when they come complaining of 'heart disease' or 'weak heart' when as a matter of fact they are suffering from the less serious condition of *indigestion*, *gastritis*, or *flatulent dyspepsia*. The pain is felt at the bottom of the sternum and in the epigastrium; it is often of a dull boring character, and radiates out towards the left breast and through to the back between the blade-bones. It is definitely connected with the taking of food, and relieved by vomiting or the eructation of wind; and these are the characters by which it must be diagnosed. In other instances, the complaint is of 'heart-burn', a burning pain felt over the lower part of the sternum, and probably due to the regurgitation into the œsophagus of the gastric contents during digestion. It is a referred pain felt in the area of distribution of the fifth dorsal nerve, and is often associated with pyrosis or water-brash, the regurgitation of acrid watery gastric contents into the throat. For the most part, however, pain due to gastric disorders (such as ulcer, new growth) is referred to the upper part of the abdomen rather than the chest.

Pains in the chest are not rare in various diseases of the *spinal cord*. Girdle pains or girdle sensations are common in *tubes dorsalis*, the patient feeling as if constricted by a hot or painful girdle. They occur early in the disease, and so are often set down vaguely to gout or rheumatism, when a more careful examination would yield early evidences of *tubes*. In *transverse myelitis*, or *fracture of the dorsal column* with injury to the cord, girdle pains round the chest may be felt at the level of the cord lesion, with loss or abolition of sensation below it; similar pains may be caused by tuberculous *spinal caries* when the upper part of the cord is compressed; if there is spinal deformity the diagnosis may be obvious, but when there is as yet no deformity it may be difficult to determine the existence of the tuberculous disease of the vertebrae unless a good skiagram is obtainable, especially one taken in the lateral or oblique-lateral position.

A. J. Jer-Blake.

PAIN IN THE EAR. (See EARACHE, p. 252.)

PAIN IN THE EPIGASTRIUM.

Sudden, severe epigastric pain may result from the rupture of a gastric or duodenal ulcer, of a gangrenous appendix, or from acute pancreatitis. The pain in such a case is attended by severe shock and signs of collapse, and it may be difficult to say to which of the above causes it is due. The past history of the patient and a careful study of the other signs present may guide one to a correct conclusion; but as all the conditions mentioned require immediate surgical treatment the differential diagnosis is made by laparotomy.

When the diagnosis of an abdominal emergency has to be considered, if the history, symptoms, and signs do not exactly fit acute intestinal obstruction, or stomach or duodenal perforation, perforating appendix, or acute cholecystitis, and yet have some resemblance of them, *acute hemorrhagic pancreatitis* is the most probable cause.

The pain of *acute intestinal obstruction* may be referred chiefly to the epigastrium. Vomiting is usually a prominent symptom in such a case. (See CONSTIPATION, p. 158; METEORISM, p. 485; VOMITING, p. 927.)

During an attack of *biliary colic* the pain may be chiefly epigastric. The restlessness of the patient in such a case is often of diagnostic value.

Chronic or recurrent pain in the epigastrium may be due to a variety of causes:

1. It should be remembered, in the first place, that epigastric pain may be due to *extra-abdominal causes*. Amongst these are *spinal caries* (especially to be thought of in children), *pleurisy*, and *intercostal neuralgia*. The first two of these can be distinguished by the usual signs: intercostal neuralgia is to be diagnosed by the presence of tender points along the course of the nerve, and by the absence of all signs and symptoms of organic disease. An X-ray examination of the chest may be required to exclude gross intrathoracic changes, such as aneurysm, before intercostal neuralgia is diagnosed finally.

A *dilated right ventricle* may be the cause of severe epigastric pain, which may even simulate the pain of gastric ulcer or gall-stones. In cases of emphysema or heart failure this should be borne in mind. In such cases the pain is aggravated by exertion.

Small *epigastric hernia* may cause recurring attacks of severe epigastric pain. They can be detected by careful palpation, usually in the linea alba.

Affections of the abdominal muscles, e.g., strain from coughing, or rheumatism (especially in children), may also cause pain in the epigastrium.

2. Assuming these to be excluded, the cause of the pain may be looked for in the following organs :

a. Stomach. The chief causes of gastric pain are carcinoma, ulcer, hyperchlorhydria, visceroptosis, pyloric stenosis, and gastralgia. (See INDIGESTION, p. 395.)

The pain in *carcinoma* is usually more or less continuous, although apt to be aggravated by food. A tumour may be felt. Vomiting is usually present, and the gastric contents show absence of free HCl in most cases : X-ray examination may be conclusive.

In cases of *ulcer* the pain is sharper, more definitely related to the taking of food, and often passes through to the back. Vomiting is usually a feature, with or without hæmatemesis. There is localized deep tenderness on pressure, often over quite a small and well-defined area. The gastric contents usually show an excess of acid.

In cases of *hyperchlorhydria* the pain is less severe than in either of the above conditions : it occurs in the late period of digestion, and is relieved temporarily by the taking of food. There is an absence of other signs and symptoms, and of local tenderness : and a test meal shows the presence of an excess of acid.

Visceroptosis and *pyloric stenosis* are diagnosed most readily by X-ray examination after a bismuth meal (Figs. 436-438) ; but the former may be suggested by the bulging lower half of the abdomen : and by the relief afforded by the wearing of a suitable abdominal support.

Fig. 436. Viscerptosis. Skigram taken in the erect posture ten minutes after giving a bismuth meal, showing the stomach to be dropped well down into the pelvis. (By Dr. W. H. Cobbell.)

Fig. 437. Viscerptosis. Skigram taken in the erect posture in the same case as Fig. 436, eight hours after the meal, showing that the stomach has emptied completely, that there is no decreased delay, but that there is pronounced ptosis of the transverse colon. (By Dr. W. H. Cobbell.)

Fig. 438. Viscerptosis. Skigram taken in the erect posture in the same case as Figs. 436 and 437 twenty-four hours after the meal, exhibiting the ptosis of the transverse colon still more clearly. (By Dr. W. H. Cobbell.)

Gastralgia should be diagnosed only when all other causes of gastric pain have been excluded. The patient is usually a young woman : the pain may occur even when the stomach is empty, but is aggravated by food, even by liquids. Vomiting is usually absent, and on physical examination there is diffusé deep tenderness over the whole of the gastric area.

Epigastric pain may also be felt to a greater or less degree in all conditions of the stomach associated with flatulence, and in that case it is relieved by the bringing up of wind. (See FLATULENCE, p. 302.)

The *gastric crises* of tabes may be attended by severe epigastric pain, and as these may occur in the pre-ataxic stage of the disease, before other signs are present, the diagnosis may be in doubt. The characteristic features are the sudden onset of the pain, and the fact that it is usually attended by urgent and persistent vomiting. There is no rise of temperature, but during the attack the blood-pressure is raised; whereas in all other forms of acute abdominal pain (except lead colic) it is lowered. Absence of the knee-jerk is not necessarily found, nor are the characteristic pupil signs of tabes.

Perigastric adhesions are a possible cause of epigastric pain, but are difficult to diagnose with any certainty. If the pain is much influenced by muscular movements, or change of posture, it is in favour of adhesions being the cause; but except for this, it has no other characteristic features. History of an operation may suggest that post-operative adhesions are the cause; or the X-ray findings may be suggestive.

b. Duodenum. The characteristic 'hunger-pain' of duodenal ulcer may be referred to the epigastrium.

c. Liver and Gall-bladder. Epigastric pain may be produced by *congestion of the liver*, either active (hepatitis), or passive, as in mitral disease. It is also produced by such conditions as hepatic abscess and carcinoma (see LIVER, ENLARGEMENTS OF THE, p. 461).

Stone in the gall-bladder may sometimes be the cause of epigastric pain, which may even be definitely related to meals, or to the taking of a particular article of food. Pressure over the gall-bladder will often elicit tenderness; and if the patient is made to take a deep breath whilst the pressure is applied there will be a painful catch in the breath as the diaphragm descends. In a doubtful case, in which the diagnosis lies between gall-stones and gastric ulcer, the following points are in favour of gall-stones: (i) The occurrence of the pain at rather long intervals, with comparative freedom from symptoms between; (ii) Long duration of the attack of pain; (iii) Continuance of the pain in spite of vomiting; (iv) The occurrence of slight shivering and rise of temperature with the attacks; (v) A comparatively low degree of acidity of the gastric contents. Gall-stones are relatively commoner in women.

d. Pancreas. Pancreatic calculi, chronic pancreatitis, or new growth, may all be the cause of epigastric pain. An accurate diagnosis of these conditions is difficult, and often impossible without laparotomy; but other signs of disturbed function of the pancreas may be present, such as fatty diarrhoea, or a 'pancreatic reaction' (p. 128) in the urine. A tumour may be felt. Glycosuria may be present, but is not invariable. In cases of chronic pancreatitis there is usually a history of gall-stones, and there are often transient periods of jaundice.

e. Abdominal Aorta.—An *abdominal aneurysm* may cause pain in the epigastrium, pain is more marked in the back. The patient is usually a man with a syphilitic history, and a pulsating expansile tumour can be felt on deep palpation. The X rays may confirm the diagnosis, though an aneurysm may exist without skiagraphic abnormality.

Abdominal angina, which is associated with arterial atheroma, with or without a high blood-pressure, is an occasional cause of severe epigastric pain, which comes on in paroxysms, especially upon exertion. The pain in such a case tends to radiate like that of true angina, and is often attended by flatulence, tenesmus, and other abdominal symptoms. There are usually signs of atheroma in the peripheral vessels; the elderly age of the patient may be suggestive; and the diagnosis may be confirmed by the yielding of the pain to vascular depressants, and especially to diuretin.

f. Colon.—Spasmodic contraction of the intestine (enterospasm) may be a cause of epigastric pain, which may simulate gastric pain by being induced by the taking of food. Such pain, however, tends to be relieved by pressure, and by the passage of gas per anum. Obstinate constipation is usually a feature of the case, and there are often mucus and shreds of membrane in the motions (muco-membranous colitis). A similar pain may be due to *plumbism*, for the diagnosis of which see p. 45.

Robert Hutchison.

PAIN IN THE EXTREMITY (LOWER). The causes of pain in the lower limbs are so numerous that much space would be required if any attempt were made to discuss

them in full. Fortunately the majority are detected easily when attention is paid to the site, nature, and history of the pain, and the painful spot is examined. An attack of gout in the big toe, an ingrowing toenail, a flat-foot, a synovitis of the knee or ankle, arterial embolism, venous thrombosis, phlebitis of a varicose vein, a tumour of one of the long bones, and many other localized pathological processes require only an elementary medical knowledge and the enlightened use of eyes and fingers for a correct diagnosis to be made. On the other hand, there are many conditions of which pain of a more or less diffused type is a prominent symptom, and which require very careful investigation if mistakes are to be avoided and diagnostic traps escaped. The fact that the nerves of the leg spring from the lower part of the spinal cord in the dorsolumbar part of the vertebral column, and that they have a somewhat lengthy course within the lumbosacral vertebral canal and the pelvic cavity, where they are comparatively inaccessible, before they reach the limb, explains why the origin of some pains referred to the lower extremity is rendered obscure. Moreover, some of the painful conditions met with are connected only indirectly with the nervous paths, and are more directly associated with morbid conditions of other structures, such as joints, blood-vessels, etc.

The classification of the various painful conditions in the lower extremity which need our attention from the point of view of diagnosis is no easy matter. One may consider first those which are primarily nervous in origin, and use them as a basis for comparison with those due to disease of other tissues.

1. Pains of Neuralgic or Neuritic Origin.

Sciatica. This name is applied commonly to a condition of the sciatic nerve which may sometimes be described as a neuralgia and sometimes as a neuritis, according to the severity of the attack and the amount of alteration in nervous function to which it gives rise. It is characterized by pain of a neuralgic type referred to a part or the whole of the course of the sciatic nerve and its branches, from the sciatic notch to the sole of the foot. Usually the pain is most severe along the back of the thigh and along the outer side of the leg. Tenderness is found on pressure over the gluteal region, over the sciatic notch, and generally all along the nerve. Exacerbation of pain is produced by stretching the nerve, for instance by flexing the thigh on the trunk with the knee fully extended. The pain is intensified by muscular exertion, and is often severe at night, especially when the patient lies on his back. Sciatica is often associated with lumbago, pain and tenderness in the muscles of the lumbar region. In long-standing cases the nutrition of the affected leg suffers and the muscles appear generally smaller than those of the other limb, but localized atrophy picking out individual muscles suggests that there is something more than a simple neuralgia or neuritis at work. Numbness, and even slight cutaneous anaesthesia, may be found on the dorsum of the foot, in the distribution of the musculocutaneous branch, in cases of simple sciatic neuritis. The knee-jerk is never affected in sciatica, but the ankle-jerk is often diminished or lost, and may remain absent for a long period after the pain has disappeared. The plantar reflex is of the flexor type.

Before making a diagnosis of sciatica or sciatic neuritis in a patient who complains of pain in the course of that nerve, the physician must satisfy himself that there is *no gross disease in the hip-joint, pelvis, or spinal column* which could give rise to the symptoms. The mobility of the hip-joint must be investigated carefully, and, if doubt exists with regard to its integrity, the joint should be skiagraphed. The pelvis should be examined externally and internally per rectum or per vaginam. The writer has seen a case of *sarcoma of the innominate bone* mistaken for sciatica, when a glance at the pelvis as a whole was sufficient to demonstrate the swelling on the affected side. In the same way the mistaken diagnosis of sciatica has frequently been made when a rectal or vaginal examination would detect a *pelvic inflammatory or malignant mass pressing on the nerve*. Even a *retroverted uterus* may sometimes cause pain in the sciatic distribution. *Tuberculous, gummatous, or malignant disease of the lumbosacral vertebrae, tumour, or meningitis involving the lower part of the spinal cord and cauda equina*, are also capable of producing pain which resembles that of sciatica. In such cases, inquiry into the action of the sphincters of the bladder and rectum may suggest the position of the lesion, and should always be made in patients complaining of sciatica. Skiagraphy of the lower part of the vertebral column may help to disclose disease of that structure, though it may be difficult to exclude *osteo-arthritis* of the lumbar vertebral joints even by skiagraphy; lumbar puncture may be necessary for diagnosing *sypilitic*

meningitis: in most cases of this kind, however, a careful scrutiny of the lower limb will show that the pain is not limited to the distribution of the sciatic nerve, that the latter is not acutely tender on pressure, that there are atrophy and paresis of certain groups of muscles, some of which are supplied by other branches of the lumbosacral plexus, that there are patches of anæsthesia corresponding to root rather than nerve areas, or that the knee-jerk is lost and perhaps the plantar reflex altered in character. Sciatica is nearly always unilateral, whereas growths or inflammation within the vertebral canal tend to produce signs and symptoms in both legs at a comparatively early stage.

The frequency with which sciatica is diagnosed when some much more serious disease is really present, is sufficient excuse for laying emphasis on the above points, and every practitioner would do well to make it his invariable rule, when faced with a case apparently conforming to the picture of sciatica, to inquire into the action of the sphincters, to inspect carefully and palpate the pelvis and spine, to make a rectal examination, and finally to keep a sharp look-out for signs of present or past malignant disease in other parts of the body. In all cases of neuralgic or neuritic pain the urine should be examined for the presence of sugar.

Anterior Crural Neuralgia and Anterior Cruritis. Neuralgia in the distribution of the anterior crural nerve is much less common than sciatica, and precautions similar to those just mentioned must be adopted before the diagnosis is made. In this condition, the pain and tenderness involve the front of the thigh as far as the knee, and the knee-jerk is sometimes diminished. In some cases the pain extends along the saphenous branch to the ankle, inner aspect of foot, and big toe. There is often considerable wasting of the quadriceps extensor muscle, which may also exhibit reaction of degeneration. Occasionally the affection is associated with sciatica.

Obturator Neuralgia. Pain in the distribution of the obturator nerve is rarely of simple neuralgic origin. *Disease of the hip-joint* and *obturator hernia* are two of the conditions which may give rise to it.

Meralgia Paræsthetica is the name given to a variety of pain which is referred to the course of the external cutaneous nerve of the thigh. The relations of this nerve to the psoas muscle and the fascia lata render it liable to stretching or pressure in standing or walking, with the result that the neuralgia is intensified by the maintenance of the erect posture. In certain instances of great obesity, prolonged sitting has been supposed to play a part in producing this type of neuralgic discomfort. There is sometimes a painful pressure-spot just below the anterior iliac spine. A flat-foot is met with not uncommonly in these cases.

Metatarsal Neuralgia, or Morton's Affection of the Foot. This neuralgia is of the paroxysmal type, and is described as dull throbbing pain in the base of the fourth—sometimes of the second—toe, and spreading up the leg. There is tenderness on pressure over the metatarsus. In a certain number of cases the pain is probably related to the wearing of tight or ill-fitting boots, or to the presence of flat-foot: but in elderly people one needs to think of atheromatous changes in the popliteal arteries, predisposing to gangrene of the foot: and in others the condition seems to be a vasomotor neurosis allied to Raynaud's disease, without the objective colour changes in the surface skin—syncope or anæsthesia characteristic of Raynaud's malady. The diagnosis general depends upon clinical judgement rather than upon any special points that can be defined in words.

Calcaneodynia is another form of pain liable to occur in neuralgic subjects who are doing much walking. The pain is often bilateral, worse in the evening and at night, and tends to spread from the heel to the base of the toes. There are no objective signs of disease. One patient who consulted me for this condition returned a year or two later with a typical brachial neuralgia. In all obscure cases of painful feet the possibility of a *gonorrhæal bursitis* or *fibrositis* should be kept in mind; and also of calcification in the posterior end of the long plantar ligament producing a spine-like projection beneath the os calcis visible to the X rays (*Fig. 439*). Calcaneodynia is also liable to be a great trouble to certain persons whose occupation predisposes them to undue exposure of the feet to changes of temperature, especially to cold: one sees the condition, for instance, in motor-car drivers, especially in the winter: it would seem to be attributable either to the pressure of leggings on the heel, or to the upward draughts that come up the foot and leg through the apertures for the brake and accelerator in the floor-boards of the car.

Multiple Neuritis. The lower extremities are often the site of multiple neuritis giving rise to great pain, but the diagnosis is rarely difficult owing to the association of atrophic palsy of the muscles, the electrical reaction of degeneration, dulling of cutaneous sensibility below the knees, and loss of the knee- and ankle-jerks. Perhaps the most characteristic and constant phenomenon in such cases is the presence of marked tenderness of the muscles on pressure. The nerve trunks are sometimes hypersensitive also, but not so constantly as are the muscles below the knees. The pain in multiple neuritis is often acute, worse at night, and aggravated by movement and the pressure of bed-clothes. *Alcohol* is a prevalent cause of such neuritis, though it may also be due to arsenic, various microbial intoxications, and so on.

Tabes Dorsalis. The pains of tabes are more often complained of in the legs than in any other part of the body. Unlike the neuralgias, they are usually bilateral and not referred to the distribution of any particular peripheral nerve. The 'lightning' pains are so characteristic that they can hardly be compared with pains of any other origin. Whether trivial and 'niggling', or so intense as to draw sweat and cries from the most heroic of sufferers, they are always short and lightning-like in duration, often rapidly repeated in the paroxysms, irregularly periodic in their attacks, and fleeting or hovering in their localization. Intelligent patients describe their lightning pains as sharp stabs, or as if the flesh had been raised and pinched between two fingers and then let go. The area in which a paroxysm of pain occurs is never much larger than the palm of a hand, and often remains hypersensitive for hours after the paroxysm has passed. It is a practical point of importance to remember that many patients, when asked if they suffer from pains, emphatically deny it, but readily admit to 'rheumatics',

FIG. 439. "Skriogram of a 'spine' on the under surface of the os calcis, causing painful heel. (By Dr. Fooking Locks.)

and then describe in a graphic manner the lightning pains of tabes. The idea of rheumatics is evolved from the fact that these pains are often provoked by changes in the weather. In addition to lightning pains, sufferers from tabes often complain of dull aching or boring pains, which are more continuous and less intermittent than those just described. Tabetic pains may precede all other signs and symptoms of the disease, in which case their diagnosis may be difficult. The following points should be investigated carefully when pains answering to the description given above are complained of: (1) A history of syphilis, congenital or acquired. The writer has known a woman, probably the subject of congenital syphilis, to suffer from lightning pains from early childhood up to forty years of age, when she presented other signs of tabes; (2) The presence or absence of a positive Wassermann serum reaction, though this test may be negative without tabes dorsalis being excluded; (3) The presence or absence of a lymphocytosis in the cerebrospinal fluid; (4) The non-reaction of the pupils to light; (5) The absence of knee- and ankle-jerks; (6) The presence of deep and superficial analgesia over the legs; (7) A history of gastric crises; and (8) The condition of the sphincter vesicæ. Particular attention is drawn to a valuable sign of tabes which is not referred to so commonly as are Argyll Robertson pupils and absent knee-jerks, i.e., the impaired pain-sensibility in the calf and other muscles when they are squeezed.

Acroparæsthesia. (See p. 545.)

2. Pain in connection with Disturbances of the Circulation.

Intermittent Claudication. This term is applied to a condition the pathology of which is still obscure, but which certainly depends on an insufficient blood-supply to the muscles

of the lower extremities when they are called into activity during locomotion. It may lead eventually to gangrene. The malady occurs chiefly in men over forty years of age, and particularly in those who have indulged freely in tobacco, who have contracted syphilis, or who have thrown strain upon their legs over a long period of time. The patient complains of pain in one or both legs, generally in the calf muscles, coming on after walking a certain distance, and disappearing with rest. The pain becomes so intolerable that he is obliged to stand or sit still until it passes off. As time goes on the distance he can walk in comfort becomes progressively shorter. Examination of the affected limbs reveals nothing obvious; they are well nourished, powerful, and normal in regard to sensation and reflexes. Probably, however, the observer will fail to detect pulsation in the arteries of the foot and perhaps he may not feel the popliteal artery behind the knee-joint. The femoral artery can usually be felt to pulsate in a normal manner. After the exertion of walking the foot may appear unduly pale; with rest, the returning flush of normal colour spreads gradually over its surface. In several cases of this kind the writer has noticed myokymia of the calf muscles; that is to say, slow worm-like contractions of individual muscle bundles without any movement of the foot. The ankle-jerk may be diminished or absent. The condition is not very uncommon, and its diagnosis is not difficult if the characteristic history of pain coming on during the act of walking is borne in mind and leads to the search for the signs referred to above. The importance of its recognition needs no emphasis in view of its tendency to go on to gangrene.

DIFFERENTIAL DIAGNOSIS OF
INTERMITTENT CLAUDICATION, RAYNAUD'S DISEASE, AND ERYTHROMELALGIA.

	INTERMITTENT CLAUDICATION	RAYNAUD'S DISEASE	ERYTHROMELALGIA
<i>Age</i>	40 and over	All ages	20 to 60
<i>Sex</i>	Males more than females	Females more than males	Males more than females
<i>Site</i>	As a rule symmetrical in calf muscles	Symmetrical in toes	Asymmetrical in feet, rarely bilateral
<i>Pain</i>	Onset while walking	During syncopal phase or absent	Precedes vasomotor phenomena
	Worse in cold weather	Unaffected by position	Aggravated by dependent posture
	Only with exercise	May be excited by cold	Cold beneficial
	No sensory change	Paroxysmal	More or less continuous, with exacerbations
<i>motor changes</i>	No sensory change	Anæsthesia and analgesia during paroxysm	Superficial and deep tenderness
	No change or slightly pale		
	Absence of pulsation in arteries. Feet sometimes cold	Pallor and lividity	Pink to purplish flush
	Gangrene occasional	Ischemia and local cold	Increased pulsation and local heat
		Gangrene common	Gangrene rare
<i>Associations</i>	Arteriosclerosis	General vasomotor disturbances	Functional and organic disease of the central nervous system
	Tobacco		
	Syphilis		

Raynaud's Disease. The pain attendant on the local syncope and local asphyxia which characterize this disease may be severe, but the diagnosis is obvious owing to the onset of symmetrical pallor or cyanosis of the toes preceding the acutely painful stage (see GANGRENE, p. 317). The hands are nearly always affected at the same time.

Erythromelalgia.—In this condition, which may affect various parts of the body, but which is seen most commonly in the feet, pain may precede any other phenomenon. The pain is more or less continuous, with paroxysmal exacerbations, and it is aggravated by the dependent position of the limb as well as by warm applications. The raising of the foot to, or above, the level of the body, and the application of cold, are attended by alleviation. Local patches of cutaneous flushing follow, or sometimes precede, the pain, and are often found about the ball of the big toe or along one edge of the foot. These

patches are generally rose-pink, but may become purplish-red in severe paroxysms. The local temperature is raised, and pulsation of the vessels may be observed. Superficial and deep tenderness is also present, but no changes in the reflexes are noted. In long-standing cases a certain amount of oedema results. Erythromelalgia occurs in persons who are apparently healthy in other respects; on the other hand, it may be an early symptom of, or be associated with, some disease of the spinal cord, such as disseminated sclerosis, tabes dorsalis, or syringomyelia.

The table on the opposite page is drawn up with a view to summarizing the chief points in the differential diagnosis of the three conditions just referred to.

3. Referred Pain in Visceral Disease. In the lower extremity the referred pain of visceral disease is not recognized so often as is that of cardiac disease in the upper extremity. Disease of the *rectum, bladder, prostate, or uterus* may, however, give rise to pain and cutaneous tenderness, chiefly in the fifth lumbar and sacral areas. Head quotes a patient who suffered from prostatitis and whose complaint was as follows: "My life is a burden, for I cannot stand owing to the pain in the soles of my feet, I cannot walk owing to the pain in my calves, or sit on account of the pain over the ischial tuberosities and in the perineum, or even lie owing to the pain in my loins and side." A careful examination of the abdominal and pelvic viscera is necessary, therefore, in all cases of pain referred to the legs without obvious local cause.

E. Farquhar Buzzard.

PAIN IN THE EXTREMITY (UPPER). Pain in some part or other of the upper extremity is a common complaint. This article makes no pretence to deal with the diagnosis of cases in which there is some obvious local source of pain, such as acute arthritis or a tumour, but is intended to serve as a guide for the diagnosis of cases in which the pain is more obscure in origin.

First, it is essential to inquire into the character of the pain, its exact site, its duration, and, if paroxysmal, its usual time of onset, its relation to movement, rest, etc. Secondly, a careful examination must be made, not only of the offending limb, but of the functions of various organs and of the nervous system in particular. The arm is innervated by branches of the brachial plexus, and the latter is made up of nerve-fibres derived from the fifth cervical to the second dorsal spinal segments through their corresponding roots. Consequently, complete examination may necessitate an investigation of the spinal functions, and an inquiry into the condition of the cervical vertebral column and the cervical meninges: it may even be desirable to take a skiagram of the neck or to make a lumbar puncture for the purpose of a correct diagnosis. Attention may be drawn especially to the fact that pain in any situation may be a forerunner, the first symptom of a nervous or spinal lesion which ultimately leads to more serious disorders of function, such as paralysis, loss of sensibility, and alteration of reflexes.

The following are various pathological conditions of which pain in the arm is often a prominent symptom:

Brachial Neuralgia. This, like neuralgia in other parts, is characterized by pain and tenderness in the distribution of one or more nerves. The pain may be referred to the course of all the branches of the brachial plexus, but sometimes is limited to that of one or two nerves, such as the ulnar, musculospiral, or internal cutaneous. It may occur only in paroxysms, but more commonly there is a constant aching discomfort, with occasional severe exacerbations excited by exertion, cold, or mental worry. The patient is generally glad to rest the limb or to carry it in a sling, in order to avoid the more acute attacks; on the other hand, the continuous aching drives him to find temporary relief in frequent changes of position. Pressure over the affected nerves is accompanied by tenderness, especially over the brachial plexus in the posterior triangle of the neck, over the musculospiral as it winds round the humerus, and over the ulnar along its superficial course in the region of the elbow. The tenderness so produced may be associated with pain or tingling referred to the more peripheral course of the nerve. The skin may be hyperæsthetic and show vasomotor changes in the way of flushing or hyperidrosis.

In making a diagnosis of brachial neuralgia it is desirable to seek for some cause to which it can be ascribed, such as a *rheumatic* or *gouty diathesis*, or a history of some preceding toxic condition, such as *influenza, malaria, or alcoholism*. In some cases no satisfactory explanation beyond unusual worry or exhaustive work in a neuropathic individual

is forthcoming. The urine should be examined for sugar, as neuralgia is sometimes of diabetic origin. The presence of muscular atrophy or anaesthesia removes the case from the category of neuralgia, and the diagnosis of neuritis or of some more gross organic affection must be substituted.

On the other hand, a *cervical rib* (Figs. 440 and 441) may produce many of the symptoms of brachial neuralgia without any definite muscular atrophy or sensory loss. In contradistinction to some of the conditions about to be described, brachial neuralgia is practically always unilateral.

Brachial neuralgia may be diagnosed, therefore, if there are pain and tenderness in the distribution of the brachial plexus without paralysis or sensory loss, and if no gross lesion can be found to account for the symptoms. So-called *muscular rheumatism* or fibrositis differs from neuralgia in that pain and tenderness are referred more to the insertions of muscles, such as the deltoid, and to the peri-arthritis tissues, especially those of the shoulder, which is often partially immobilized by fibrous adhesions; and small tender fibrous masses can usually be felt, particularly in the suprascapular region.

An acute brachial neuralgia, lasting only a few hours or two or three days, is sometimes the first symptom in epidemic encephalitis.

Brachial Neuritis. When muscular atrophy and sensory loss are found in addition to pain and tenderness, the condition must be regarded as one of neuritis.

Unilateral brachial neuritis is uncommon except as a result of some gross lesion, such as pressure on, or irritation of, the nerve-trunks. Bilateral brachial neuritis is common enough, but is then a part of a multiple peripheral neuritis due to alcohol, arsenic, lead, diabetes, etc., in which the lower extremities also are generally involved.

Before making a diagnosis of one-sided brachial neuritis, careful search must be made for evidence of such conditions as *cervical rib*, *tumour in the posterior triangle of the neck*, *glands in the axilla*, *aneurysm of the subclavian artery*, *malignant disease or caries of the cervical vertebrae*, *cervical pachymeningitis*, *spinal tumour*, or *spinal gliosis*. *Neuromata* or *fibro-neuromata* are generally distributed widely about the peripheral nerves, but cases have been recorded in which they have been limited to the brachial plexus and have given rise to a brachial neuralgia or brachial neuritis. Such tumours may be so small as to escape observation unless examined by minute palpation. *Adiposis dolorosa* (p. 509) is another rare condition which may give rise to neuralgic pain in the arm, but it is not limited to one limb.

Cervical Ribs. A supernumerary seventh cervical rib, unilateral or bilateral, is a frequent congenital abnormality. In a small proportion of cases it may give rise to symptoms, especially in adults who use their arms and hands continually in the course of their employment. Women suffer more often than men. Pain radiating from the root of the neck to the tips of the fingers, more often than not along the ulnar border of the arm, is usually the first, and may be the only, symptom. The pain is of an aching or dull boring character, and is much influenced by rest and position; for instance, if a woman, who has been suffering much when at work, takes a holiday, and ceases to use her arms for scrubbing, lifting, etc., she may lose the pain altogether until she resumes her

Fig. 440.—Skiagram showing cervical ribs in the case of a child. (By Dr. S. Gilbert Scott.)

Fig. 441.—Skiagram of cervical ribs in an adult. On the left side of the skiagram the rib is fully developed; on the right side only a part is bony, so that it forms a false or buttress rib continued by a fibrous cord, which does not show with the X rays. (By Dr. S. Gilbert Scott.)

occupation. Similarly the pain is worse at night after a day's work, and may be influenced favourably by keeping the arm in certain positions. Lying in bed with the hand behind the head is a favourable attitude in many cases. Very occasionally the pain spreads into the scapular region along the course of the suprascapular nerve. There is rarely any tenderness along the peripheral parts of the nerves, but pressure in the posterior triangle of the neck, just above the inner part of the clavicle, may give rise to pain radiating down the arm.

In addition to pain there may be disturbances of motor, sensory, and vasomotor origin. Atrophic palsy of the intrinsic hand muscles and of the flexor muscles in the forearm are the common motor disturbances, and may lead to deformities such as CLAW-HAND (p. 141). Anaesthesia along the ulnar border of the forearm, and perhaps extending on to the inner fingers, is observed sometimes. Intense vasomotor disturbances may be produced without definite muscular atrophy or sensory loss, both hands being the seat of painful cyanosis involving the fingers, and almost amounting to the condition seen in Raynaud's disease. Sometimes there is a diminution in the radial pulse on the affected side. The diagnosis of cervical rib or ribs depends on the use of the X rays (*Figs. 440, 441*) to reveal their presence, but it must be borne in mind that the pressure on the trunk or trunks of the brachial plexus is usually exerted by a fibrous band passing from the tip of the cervical rib to the first dorsal rib, and that therefore the size of the rib shown by skiagraphy affords no guide as to the importance of its effect. The most rudimentary rib is as important from this point of view as one which is fully developed.

Acroparæsthesia. This term is applied to a fairly common complaint, usually made by women between thirty-five and fifty-five years of age, who are continually using their hands, and especially by those whose hands are frequently immersed in waters of different temperatures. Charwomen, domestic servants, needlewomen, and washerwomen are particularly liable to suffer. Many of the victims indulge to a moderate extent in spirit-drinking. They complain of a burning pain, associated with tingling and numbness, in the fingers and palms of their hands. It is noticed chiefly in the latter part of the day after work is over, and becomes intensified when they are warm in bed. In the early morning their fingers are numb and clumsy, but the discomfort passes off while they are at work, only to return again towards evening. As a rule there is little to see on examination, but there may be redness or pallor of the affected parts, associated with a subjective feeling of heat and swelling. Sensibility is unimpaired if allowance is made for the cutaneous thickening usually present in persons whose hands are much exposed to moisture and friction. There is no definite palsy or muscular atrophy. Acroparæsthesia as a rule affects both hands, and very occasionally it is accompanied by a similar condition in the feet.

Similar paræsthesiæ are sometimes complained of by patients suffering from *tubæ dorsalis*, but in those cases the pains are of the lightning character, and never limited to the hands. Other tabetic signs, such as Argyll Robertson pupils, ulnar analgesia, impaired sense of position, and absence of tendon-jerks, serve to make a diagnosis. In the early stages of *subacute combined sclerosis of the spinal cord*, paræsthesiæ, sometimes of a markedly painful character, are referred to the hands and feet. The presence of some ataxia or spastic paraplegia, with increased tendon-jerks and extensor plantar reflexes, differentiates this disease from the ordinary acroparæsthesia.

Radicular Pain. Under this title may be included all pains in the arm which radiate through the peripheral distribution of the posterior spinal roots from the fifth cervical to the second dorsal. These pains extend from the neck towards the periphery of the limb, and are usually of a sharp, lancinating type. In the large majority of cases they are produced by some gross morbid process involving the roots within the spinal canal or in their course through the intervertebral foramina. The morbid processes most commonly responsible are *intravertebral tumour*, *cervical pachymeningitis*, *cervical caries*, and *malignant disease of the cervical vertebrae*. In all these conditions the radicular pain may precede all other symptoms, with the result that the diagnosis is often difficult and sometimes impossible until further phenomena develop. The pain is occasionally unilateral, more often bilateral; there may be tenderness on pressure over the vertebrae, especially in the case of cervical caries or malignant disease. Movements of the neck will intensify the pain in the latter conditions. The diagnosis is arrived at by careful attention to the following

points : (1) Evidence of deformity, rigidity, or tenderness of the cervical vertebrae, supplemented by an X-ray examination (*Figs.* 619, 620, pp. 795, 796); (2) The presence of other root symptoms, such as localized atrophic palsy, anaesthesia, and loss of tendon-jerks in the arms; (3) Evidence of pressure on the spinal cord, producing spastic paralysis of the trunk and lower limbs, together with anaesthesia, loss of abdominal reflexes, increased knee-jerk, ankle-clonus, and extensor plantar reflexes; (4) The occurrence of oculo-pupillary phenomena when the eighth cervical and first dorsal roots are involved; and (5) The condition of the cerebrospinal fluid obtained by lumbar puncture (p. 382).

In addition to the gross extrinsic processes affecting the spinal roots, there are other cases in which a spinal root is the site of an intrinsic inflammatory or vascular lesion. *Herpes zoster* is a common result of such a lesion, and may be found in the peripheral distribution of any of the posterior roots which go to form the brachial plexus. Pain in the upper extremity often precedes the eruption, and post-herpetic neuralgia is sometimes long persistent and associated with marked hyperaesthesia in the corresponding root area. Uniradicular pain, followed by atrophy of the muscles supplied by the efferent root fibres and by sensory loss in the region innervated by the afferent fibres, with or without the development of an herpetic rash, also occurs in rare instances as the result of an inflammatory or vascular lesion of the spinal nerve in the neighbourhood of the posterior root ganglion.

Referred Pain in Visceral Disease. In disease of the heart and aorta, especially with syphilitic disease of the aortic valves, or with atheroma or aneurysm of the first few inches of the aorta, attacks of pain in the left arm are often complained of. These may be confined to the arm, or may be associated with fully developed angina pectoris. The pain is radicular in distribution, referred to the first and second dorsal root areas—the ulnar border of the arm—sometimes extending into the little finger. During the attacks cutaneous hyperaesthesia may be present over the same areas. In all cases of paroxysmal pain referred to the left arm a careful examination of the thoracic viscera is therefore indicated.

Occupation Neuroses.—The upper limb is the common site of occupation neuroses, termed writer's cramp, typist's cramp, and so on, according to whether it has to do with writing, typing, needlework, telegraphy, hair-cutting, etc. These neuroses are mainly characterized by some form of muscular spasm, but pain of a cramp-like character is a frequent accompaniment of the spasm. The diagnosis is easy, because careful inquiry will elicit the fact that the pain and spasm are evoked by the employment of the limb in a particular occupation, and that other manipulations involving the use of the same muscles may be carried out with impunity. The acute pain which is associated with the spasm may be followed by a dull aching for some hours after the occupation has been indulged in.

sychalgia.—Finally, the term *psychalgia* may be applied to pain referred to the arm, as to other parts of the body, by patients whose nervous and mental resistance is undermined or exhausted. Neurasthenic pain of this kind is rarely limited to the arm; it is referred more commonly to various parts of the head and to particular regions along the course of the vertebral column.

E. Farquhar Buzzard.

PAIN IN THE EYE is not by itself pathognomonic of any particular lesion; but it may be complained of under very diverse circumstances, which may be ranged into the following groups:—

1. Pain associated with Visible Inflammatory Changes, due to:—

Foreign body	Ulceration of the cornea	Irido-cyclitis
Entropion	Interstitial keratitis	Glaucoma
Conjunctivitis	Iritis	Ocular herpes.

The differential diagnosis between these is discussed in the article on EYE, ACUTE INFLAMMATION OF (p. 285).

2. Pain without Visible Changes in the Eyeball, but with Acute Loss of Sight in one eye only, in both eyes together, or in one eye after the other: Retrobulbar neuritis.

The pain is generally referred to the back rather than to the front of the eye. The diagnosis is suggested at once if considerable loss of sight comes on acutely in an eye which

on examination proves not to be affected by glaucoma, intra-ocular hæmorrhage, detachment of the retina, or any visible or palpable lesion, especially if the degree of vision power waxes and wanes owing to varying degrees of engorgement of the vessels in the optic nerve where it is inflamed between the eyeball and the brain. After days or weeks, the pain may disappear and sight return to normal : on the other hand, in severer cases, the inflammation in the optic nerve may come forward to the back of the eyeball and become visible as optic neuritis (*Fig. 418*, p. 518). The cause of the mischief may be difficult to determine : often it remains obscure : sometimes it is traced successfully to plumbism, syphilis, or to some acute infection such as influenza or a toxic-absorptive malady arising from septic teeth, intestinal toxæmia, septic tonsils, pelvic sepsis, and so on.

3. Pain without Inflammation and without Blindness, but associated with errors of refraction : Eyestrain.

The commonest cause of eyestrain is some error of refraction, especially hypermetropia, astigmatism, or presbyopia, and it arises mainly in persons whose occupation entails much reading of small print, fine needlework, or close attention to minute details near to the eyes : or in those whose work has to be carried on in too dim or too strong a light especially electric or strong sunshine. It is not so much the big degrees of error of refraction that cause the mischief, for these are generally so obvious to the patient that they have been corrected already by appropriate glasses : it is rather the minor or even quite small degrees of hypermetropia or astigmatism that are responsible, for these have very likely not by themselves led the patient to seek ocular advice : and they need considerable care in their detection even at the hands of a skilled ophthalmic surgeon. The patient may consider that he has exceptionally good sight, especially in the case of minor degrees of hypermetropia, which may none the less cause not only severe pains in the eyes, but also serious headaches or attacks simulating migraine. Frequently it is only when the patient has become tired from excessive work that the strain of accommodating for near objects begins to tell : and the symptoms may be attributed to overwork when this is but partly true : or presbyopia may produce pain in eyes which were not subject to eyestrain when the faculty of accommodation was more lissom in youth, notwithstanding the error of refraction. Pain in the eyes from eyestrain becomes more common as age advances, and some elderly persons are scarcely able to read or work at all on this account, even when glasses have been prescribed.

On the other hand, work carried out under exceptional circumstances of light or closeness may cause eyestrain even in those whose ocular refraction is normal or fully compensated by glasses : microscopists are liable to suffer in this way for instance, as are those who are exposed to the glare of sunshine upon snow, or workers with acetylene blow-pipes, and so on. The circumstances of the case are likely to suggest the diagnosis.

4. Pain in the Eyes due to Febrile or other Constitutional Causes. The most familiar example of cases which come under this heading is *influenza*. The pain is generally referred rather to the backs of the eyeballs than to the eyes themselves, but nevertheless the complaint is one of pain in the eyes. The trouble occurs both as an early symptom of the disease and as a sequela when the fever has subsided. The diagnosis is made from the course of the pyrexia and the general symptoms : but influenza should not be regarded as certain without bacteriological confirmation, for it is usually guessed at rather than diagnosed and often wrongly. In a similar way pain in the eyes may form part of the clinical picture in many other fevers, notably small-pox, typhus, typhoid fever, measles, secondary syphilis, and malaria. The diagnosis is influenced very little by the fact that the patient complains about his eyes except when there is coryza as well as pain, for instance in the early stages of measles. In other conditions, such as meningitis, there is *Photornobia* (p. 639) rather than pain in the eyes, and reference may be made to the article upon that symptom.

5. Pain in the Eyes due to Inflammation in Ethmoid, Sphenoid, or Frontal Air Sinuses.—The diagnosis of these conditions depends upon special skill in investigating the state of the accessory nasal air spaces, and even a specialist may fail to detect infections that exist in them. With frontal sinus disease the pain is more over the eye than behind it, but in ethmoidal or sphenoidal air-cell catarrh pain behind the eyes may be the main thing complained of.

Herbert French.

PAIN IN THE FACE.—The distinction between pain in the face and pain in the head, though to some extent artificial, is sufficiently marked in most instances; the latter with its diagnostic significance is discussed under HEADACHE (p. 369). There are certain etiological points, however, at which faccache and headache overlap: for example, the supra-orbital pain and the headache which may both originate from ocular errors of refraction. Pain in the face, as elsewhere, may be due to very obvious causes, which need no discussion, such as an inflamed parotid gland, a gumboil, or an acute conjunctivitis. On the other hand, pain in the face may be complained of when superficial, and perhaps minute, examination fails to discover an adequate basis. Guidance towards the correct diagnosis of such cases may be obtained by a consideration of the course, signs, and symptoms of the following clinical types of facial pain.

Major Trigeminal Neuralgia (*tic douloureux* or epileptiform neuralgia) may be regarded as a distinct disease, owing to the general similarity of one case to another. Its pathology is unknown, but in each case the pain is attributed in its early stages to some local defect, such as a carious tooth, and many sound, as well as many diseased, teeth are removed in a vain endeavour to arrest the malady. Beginning usually after thirty-five years of age, *tic douloureux* is characterized by paroxysms of acute pain in the distribution of one or more of the divisions of the trigeminal nerve, generally of one side only. The intervals between the paroxysms vary from seconds to months, and may be influenced in their length by many factors, such as the general state of health, mental worry, and exposure to cold. The intervals tend to become shorter and the paroxysms more severe and more extensive in their distribution. The pain is described as beginning in spots beneath the skin, and radiating along the peripheral branches of the nerve. These spots correspond to points where the nerve bundles penetrate the deeper tissues to reach the superficial structures, and may be recognized as places pressure upon which is particularly liable to start an attack. In severe cases, the lightest touch, a breath of wind, attempts at articulation or mastication, and even the act of defecation may be sufficient to provoke an agonizing spasm in which the violent reflex contraction of the muscles of the corresponding side of the face affords some evidence of the suffering endured. During the paroxysms the patient may endeavour to obtain relief by firm pressure or rough friction with his hand over the starting-point of the pain. The attack may be accompanied by cutaneous flushing, photophobia, lachrymation, and salivation, as well as by a subjective sensation of swelling in the affected tissues. When the tongue is affected a metallic taste is sometimes described by the sufferer. Trophic changes in the hair and skin are also observed as a result of repeated attacks. The diagnosis of major neuralgia depends chiefly on the following points: (1) The age of onset; (2) The absence of relief or only temporary alleviation afforded by removal of possible exciting causes, such as defective teeth; (3) The presence of definite starting-points of the pain corresponding to exits of branches of the fifth cranial nerve, and the spread of the pain along the corresponding nervous paths; (4) The paroxysmal character of the pain, its intense severity, and its unilateral distribution; (5) The excitability of the attacks by peripheral stimuli; and (6) The various reflex, vasomotor, secretory, and trophic phenomena to which the attacks of pain give rise. From a practical standpoint the most important task in diagnosis is to discriminate between cases of idiopathic major neuralgia and those which belong to the next group.

Trigeminal Neuralgia due to Organic Lesion of the Nerve or its Roots. This form of neuralgia may simulate *tic douloureux* in every particular, and its diagnosis can be made only by careful systematic examination of the patient, with the possibility of an organic lesion being the source of pain before the physician's mind. *Tumours at the base of the brain* in the middle fossa, *tumours growing from the base of the skull* in the neighbourhood of the foramen ovale and foramen rotundum, as well as *tumours of the cranial nerves* themselves, are amongst the causes of trigeminal neuralgia. *Gummatous meningitis* and *gummatous periostitis* may be mentioned in the same connection. In every case of trigeminal neuralgia, therefore, headache and vomiting should be inquired after, optic neuritis looked for, and the Wassermann reaction tested; lumbar puncture and examination of the cerebrospinal fluid may be necessary. Examination of the functions of each cranial nerve must be carried out, and in particular those of the fifth nerve carefully tested. Any impairment of sensibility in the cutaneous territory of this nerve must be regarded as evidence that the case is not one of idiopathic neuralgia, and the same may be said when there is impaired

motor power in the muscles of mastication. In several cases of severe trigeminal neuralgia I have found atrophic palsy of the masseter and temporal muscles on the same side, with slight anaesthesia on the face, and these cases have always proved to be instances of growth involving the structures at the base of the skull. In one patient the neoplasm originated in the sphenomaxillary fossa.

Trigeminal neuralgia may also occur as the result of intrinsic disease of the Gasserian ganglion, e.g., in cases of *herpes zoster*. This condition is fairly common in the distribution of the first division of the trigeminus, much less common in that of the second and third. The pain usually precedes the herpetic eruption by some days, and is associated with constitutional malaise and sometimes with pyrexia, two important points in diagnosis. The latter becomes clear with the development of the rash, but even then it is necessary to bear in mind the possibility that the Gasserian ganglion may be affected by gross external disease, such as neoplasm or gumma, or an extension of bony disease. In persons over fifty years of age it is found frequently that pain of a neuralgic character persists after the herpes has disappeared, and may last for months and even years. Careful examination may discover cutaneous marks corresponding to the site of the previous vesicular eruption.

Neuralgia Minor. Under this heading may be classed the varieties of facial pain which are secondary to disease of various local structures, such as the teeth, the eye, the ear, the nose, and the tongue. The pain can be distinguished by certain features as belonging to one or other of two types. The first is a true neuralgia, that is to say a pain which is distributed along the course of one or more divisions of the trigeminal nerve, usually starting in the neighbourhood of the diseased structure and associated with tenderness along the affected branches of the nerve. The second is a visceral pain, referred to some spot which may be at a distance from the disease, in which case it is usually not accompanied by decided tenderness along the course of the nerve to which the pain is referred, though there may be superficial hyperaesthesia.

The history of a *decaying tooth* affords an example of how these types of pain may arise. In the early stages of caries the pain is limited to the tooth. With inflammation and destruction of the pulp, pain is referred to a segmental area on the surface of the face varying with the particular tooth implicated: thus a diseased canine tooth is associated with pain and tenderness in the naso-labial area (*Fig. 442, Na-L*); after the pulp is dead, local suppuration may start a neuralgia which may not only spread along the nerve branch which supplies the tooth socket, but may extend into neighbouring branches and into other divisions of the trigeminal nerve. The maximal points in the segmental areas referred to are shown in the accompanying diagrams (*Figs. 442-445*), and the general relationship between individual teeth and their segmental areas may be described as follows:

UPPER JAW.

Incisors	Fronto-nasal	1st molar	Maxillary
Canine	Naso-labial	2nd	Mandibular
1st bicuspid	"	3rd	"
2nd	Temporal or maxillary		

LOWER JAW.

Incisors	Mental	1st molar	Hyoid
Canine	"	2nd	"
1st bicuspid	"	3rd	Hyoid or superior laryngeal.
2nd	Doubtful		

The value of this knowledge in relation to diagnosis lies in the fact that pain, with tenderness, referred to any one of these segmental areas should lead the observer to seek for its cause in disease of the corresponding tooth.

The headache, sometimes called neuralgia, which results from *errors of refraction*, especially astigmatism, is referred to the mid-orbital area, where superficial tenderness may often be discovered on examination. This form of pain comes on in the morning as soon as the eyes are opened, and is intensified by reading or sewing. It disappears under the use of atropine, and wears off of itself if the eyes are not used for near work. Occasionally it takes on a paroxysmal character without any particular relationship to the use of the eyes. With *iritis* and *glaucoma*, referred pain may be intense, and it is usually

PAIN IN THE FACE

situated in the temporal and maxillary segmental areas as well as in the eyeball itself. The occurrence of referred pain in chronic glaucoma without pain in the eyeball is a point which may be of great diagnostic importance, as it may draw attention to the unsuspected ocular disease.

With *ear disease* the hyoid area is that to which pain is referred and in which hyperæsthesia of the skin may sometimes be found; in the more severe types of disease, such as suppuration in the middle ear, the pain may also be referred to the vertical and temporal areas of the scalp.

Lesions of the tongue may produce, in addition to local pain in the organ itself, referred pain in three other areas: the mental area when the disease affects the anterior portion of

the tongue; the hyoid area when the lateral portion is involved; and the occipital area when the dorsum is the site of the lesion.

With inflammatory affections of the *nose* and *frontal sinuses*, pain is referred to the fronto-nasal and mid-orbital areas on the forehead; with sphenoidal sinusitis occipital pain is often complained of.

The various forms of pain in the head associated with *disease of the thoracic and abdominal organs* are discussed under HEADACHE (p. 369), and the same article deals with the aches which accompany general constitutional diseases.

In *tubes dorsalis* pains are sometimes described in the face, and have the same characteristics as those in other parts of the body. They are paroxysmal, sudden, severe, and

lightning-like. They are rarely limited to the face. They may be accompanied by a more continuous, dull, boring kind of pain. The diagnosis is easy if a systematic examination of the nervous system is carried out.

Pseudo-neuralgias, or psychalgias, which are complained of by hysterical and neurasthenic individuals, are vague in their distribution, not limited to the trigeminal area, and often bilateral. They tend to disappear when attention is drawn in other directions, and are less intense during eating and talking. Their diagnosis depends not only on the exclusion of organic disease, but on the discovery of some mental disturbance which adequately explains their occurrence.

E. Farquhar Buzzard.

PAIN IN THE FOOT. (See PAIN IN THE EXTREMITY, LOWER, p. 538.)

PAIN IN THE FOREARM. (See PAIN IN THE EXTREMITY, UPPER, p. 543.)

PAIN, GIRDLE. (See GIRDLE PAIN, p. 326.)

PAIN IN THE HAND. (See PAIN IN THE EXTREMITY, UPPER, p. 543.)

PAIN IN THE HEAD. (See HEADACHE, p. 369.)

PAIN IN THE HEEL. Pain in the heel is often a symptom which may be troublesome and persistent without any adequate cause for it being found; children often limp from it and yet one may find little wrong; the cause is then usually either the effect of some forgotten injury or strain or else a thorn or other foreign body; in older people a cause that needs bearing in mind is calcification of the posterior end of the long plantar ligament forming a spine on the under surface of the os calcis, productive of continued and troublesome pain in the centre of the under part of the heel, the diagnosis depending on detection of this spine with the X rays (*Fig. 439*, p. 541). There are many other possible causes, however, the chief of which may be tabulated as follows:

The effect of constant jarring of the heel, as from walking on hard roads

Cornification of the skin

Chilblain of the heel

Pressure soreness over the tendo Achillis from boot, shoe, or legging

Bursitis between the tendo Achillis and the os calcis

Injury:

Tearing of ligament fibres near the insertion of the tendo Achillis

Tearing of ligament fibres below the internal malleolus

Tearing of ligament fibres below the external malleolus

Tearing of ligament fibres of the long plantar ligament

Cracking or fracture of the os calcis

Detachment of the hinder end of the astragalus

Bruising of the periosteum of the os calcis

Fibrositis of the soft parts of the heel

Gout in the heel

Periostitis of the os calcis

Tuberculous caries of the os calcis

Foreign body, such as pin, needle, or thorn

Sarcoma of the os calcis

Spine of the os calcis.

The differential diagnosis depends upon obtaining a clear history of how the pain began, exactly where it is, and what produces it; upon inspection of the part for local discoloration or swelling; upon palpation, to locate the precise site of the pain, and particularly of any tenderness, especially if the latter is increased by movement; and upon the results of X-ray examination of the part for fracture, caries, foreign body, or spine.

Constant *jarring* of the heel such as may be produced by walking in thin shoes on hard roads, or by occupations which involve the use of the foot on vibrating surfaces or instruments, may cause pain in the heel resulting partly from periostitis of the os calcis, partly from thickening of the soft parts involving the nerves; the thickening may affect the skin and produce a visible and palpable *cornification* of the skin in the form of a diffuse rather than a localized corn, though localized corns may be found also on the heel sometimes just as they are on the toes.

Chilblain of the heel is commoner on the posterior than on the under aspect; it is particularly common over the tendo Achillis just above the top of the back of the shoe, and the short skirts of to-day render this affliction more prevalent in girls and women than it used to be. The trouble is apt to be bilateral, and is indicated by its occurrence in cold weather, by the purplish discoloration of the skin, and by the way the skin and soft parts are thickened and tender. The liability to chilblain is increased by the effects of

pressure over the *tendo Achillis*, not only by boots or shoes, but by the lower edges of leggings, and drivers of motor-cars are apt to be afflicted in this way as the result of pressure of footwear on the *tendo Achillis* as the result of plantar-flexion of the foot in using clutch-pedal, accelerator, and brake.

Bursitis of the bursa lying between the *tendo Achillis* and the *os calcis* may be very painful without obvious swelling or discoloration; or there may be local swelling on either side of the lower part of the *tendo Achillis*. The diagnosis depends on accurate localization of the site of the tenderness and pain. The trouble may be associated with chilblain and pressure effects or may result from local injury; or, again, it may be purely inflammatory, this bursa being more prone than others to be affected by gonococcal bursitis. Signs of gonorrhœa should be looked for, though, as in the case of gonococcal synovitis, arthritis, or iridocyclitis, the bursitis may develop a long time, even years, after the acute stages of actual gonorrhœa have passed and become forgotten.

Injury is a common cause of pain in the heel, often lasting long after the injury occurred. It may be difficult to decide just what form the effects of the injury have taken; X-ray examination will be needed to diagnose or exclude *cracking or fracture of the os calcis* or *astragalus*; if there is no proof of bone affection, the trouble will probably be in connection with either ligamentous fibres or the periosteum, and the further diagnosis will depend upon what spot is found to be most tender on palpation and manipulation; tearing of ligamentous fibres attached to the internal malleolus will cause local, and possibly acute, tenderness well below the ankle on the inner aspect of the heel; of the similar fibres from the external malleolus, on the outer aspect; of the *tendo Achillis*, behind and to one or other or both sides of the posterior aspect of the heel; of the long plantar fascia, often resulting from a stumble or from a jump from a height, inferoposteriorly.

Fibrositis of the soft parts of the heel, or *gout*, or *periostitis* of the *os calcis*, will be much alike, and may simulate the effects of injury; indeed, injury may be but a factor bringing out the effects of any of the three. No local examination will serve to settle which is which; the diagnosis will depend upon collateral evidence of fibrositis, or of gout, in the form of lesions due to these causes elsewhere—lumbago, sciatica, rheumatoid arthritis, myalgia, neuritis, tophi in the ears, or an obvious history of gout in the big toe on previous occasions. Periostitis will only be distinguishable from inflammatory affections of the other soft parts by the locality of the tenderness, and by the depth at which the tenderest part seems to be. The lay name for all these things would probably be ‘rheumatism in the heel’.

Tuberculous caries of the *os calcis* is fortunately rare; in the earlier stages it is apt to simulate the effects of injury, strain, sprain, or fibrositis; and only when the trouble persists and increases does the more serious diagnosis compel consideration, X-ray evidence of the state of the bone clinching it. There may be no decided swelling at first; later there will be local swelling, though the latter may seem to be of the soft parts rather than of the bone.

Foreign body in the heel is by no means uncommon; if it is a metal body, such as a needle, part of a nail or tin-tack, diagnosis is easy enough with the X rays; commonly, however, especially in children, or in adults who have been walking barefoot at the seaside on their summer holidays, a thorn may have run in without certain knowledge on the patient's part, and the thorn may not be demonstrable with the X rays. A local corn with a tender open centre may develop where the thorn went in, and it may be weeks before the true nature of the trouble becomes manifest through this corn festering and the thorn coming out.

Sarcoma of the os calcis is extremely rare; it causes swelling of the heel before pain; the swelling is progressive, and the diagnosis is made by X-ray examination followed by operation. The sarcoma is myelomatous or endosteal rather than periosteal, and it is proportionately less rapid or malignant.

Spine on the under surface of the os calcis is quite a common lesion, but it is often forgotten, and many a patient suffering from the pain in the heel due to it is treated for fibrositis or gout or injury instead because no X-ray plate is taken. X rays make the diagnosis obvious (*Fig. 439*, p. 541). It is a malady of the second half of life rather than of earlier years, and it is suggested when the tender spot to deep palpation is on the under surface of the heel, in the middle line, about one inch or a little more from the back of the foot.

Herbert French.

PAIN IN THE HYPOCHONDRUM (LEFT). Pain in the left hypochondrium may proceed from :

The Stomach. Any painful condition of the stomach may cause pain below the left costal margin ; particularly a new growth or an ulcer towards the cardiac end. For the differential diagnosis, see INDIGESTION, p. 395, and PAIN IN THE EPIGASTRIUM, p. 536. Flatulent distention of the fundus may also be a cause, diagnosed by the fact that the pain disappears on eructation ; it is a common result of aerophagy.

The Gall-bladder. In cases of cholelithiasis the pain is sometimes referred to the left hypochondrium (see PAIN IN THE EPIGASTRIUM, p. 536).

The Spleen. Some enlargements of the spleen are painful (see SPLEEN, ENLARGEMENT OF, p. 774) ; or the pain may be caused by perisplenitis, in which case a friction sound can sometimes be heard on auscultation over the organ.

The Left Kidney. Stone in the left kidney may cause pain which has the characters described in the section on pain in the right hypochondrium (see below). A movable left kidney is rarely a cause of pain. A perinephric abscess may cause pain, as it does in the right hypochondrium.

The Colon. A new growth in the splenic flexure of the colon, or obstruction of the large bowel lower down, may cause pain in the left hypochondrium ; in the former case a tumour can usually be felt on bimanual palpation ; in the latter, signs of chronic obstruction will be present (see CONSTIPATION, p. 158). Apart from growth, a mere *accumulation of faeces* in the transverse and descending colon may cause a feeling of pain and weight in the left hypochondrium. The disappearance of the pain after the administration of a few large enemata will establish the diagnosis.

Pleurisy, Intercostal Neuralgia, and Herpes Zoster may all cause pain in the left hypochondrium. In the first of these a friction-sound will be heard ; in intercostal neuralgia there will be tender points over the course of the intercostal nerve ; in the case of herpes, the cause of the pain will be cleared up by the appearance of the eruption, but pain may persist long after this has disappeared.

Abnormal mobility of the lower intercostal joints may cause pain—a condition which is called *slipping rib*. The pain may be very severe and come on with exertion, especially when this involves stooping and bending. It is sharp and stabbing at first, but may be followed by a dull ache lasting all day. It may easily simulate the pain of a deep lesion. The slipping rib may be felt on careful palpation, but in most cases the condition is suggested by the patient's own story of how the pain is brought about. It is apt to be mistaken for gastric ulcer on the left side, gall-stones on the right.

Subdiaphragmatic Abscess. (See p. 555.)

Robert Hutchison.

PAIN IN THE HYPOCHONDRUM (RIGHT). The differential diagnosis of the cause of pain in the right hypochondrium is often a matter of great difficulty ; it may proceed from any of the following organs :

Liver and gall-bladder
Duodenum
Head of the pancreas
Right kidney
Appendix vermiformis

Colon
Uterine appendages
Intrathoracic disease
Affections of the spine or chest wall
Subdiaphragmatic abscess.

The diagnosis is rendered still more difficult by the fact that disease may easily be present in more than one of these situations at the same time.

Liver. Various forms of enlargement of the liver are apt to be attended by pain in the right hypochondrium, e.g., hepatitis, passive congestion, hepatic abscess, carcinoma (see LIVER, ENLARGEMENTS OF THE, p. 461).

Disease of the Gall-bladder must also be thought of, e.g., gall-stones, cholecystitis, and carcinoma ; in these it will usually be found that there is tenderness on pressure over the gall-bladder, with the characteristic catch in the breath when the patient is asked to take a deep inspiration while the fingers of the observer are pressed in over the organ ; in acute cholecystitis there will be pyrexia, and probably rigors.

The pain of *biliary colic* may be felt chiefly in the right hypochondrium, but tends to radiate through to the back and up towards the right shoulder. It may be simulated

closely both by the kinking of a movable kidney and by renal colic (see below). When the attacks occur during the night as well as in the day, it is in favour of biliary colic.

It must be noted specially that the absence of jaundice in no way contra-indicates a diagnosis of gall-bladder disease.

Duodenum.—A *duodenal ulcer* may cause deep-seated pain in the right hypochondrium, which usually has the character of hunger-pain (p. 342). Pain due to chronic cholecystitis or appendicitis, however, may also have this character, and an exact differentiation of them may not be possible without exploration. The pain in duodenal ulcer, however, occurs in more definite attacks with long intervals of freedom; it is often nocturnal, waking the patient in the small hours of the morning. Duodenal ulcer is commoner in men, disease of the gall-bladder in women, whilst appendicitis may occur with almost equal probability in either sex. The percentage of free HCl in the stomach contents is more persistently high in duodenal ulcer than in either appendix dyspepsia, or gall-stones. A history of melæna, or the presence of occult blood in the faeces, would determine one in favour of ulcer, and this may be confirmed by X-ray examination, which will show a small, hypertonic and rapidly emptying stomach with some deformity of the duodenal 'cap' in most cases of duodenal ulcer, unless the latter stenoses the duodenum, when the X rays will show a dilated stomach and bismuth still present after eight hours—an indication for surgical treatment, the diagnosis being established at the operation.

Pancreas. Malignant disease of the pancreas may cause pain in the right hypochondrium. In such a case a deep-seated tumour may be felt, and there is often jaundice along with a distended gall-bladder. On the other hand, when gall-stones lead to jaundice, the gall-bladder is not usually distended (see JAUNDICE, p. 405).

Right Kidney.—A freely *Movable Right Kidney* may, by ureteral kinking, cause sudden attacks of pain in the right hypochondrium which may exactly simulate gall-stone colic. Indications of intermittent hydronephrosis should be looked for, e.g. the appearance of a renal tumour, and the occasional discharge of large quantities of urine; urinary symptoms, however, may be entirely absent. The attacks tend to occur by day, whilst biliary colic often begins in the night; a certain diagnosis may be impossible without pyelography (p. 445).

Stone in the right kidney may cause chronic pain in the right hypochondrium and back. The kidney may be enlarged and tender on bimanual palpation in such a case; the urine may furnish no diagnostic indication, but frequently there is slight albuminuria, often intermittent. The X rays, however, may make the diagnosis clear (*Figs. 354-356*, pp. 440, 441), although a negative result does not exclude the possibility of stone. Ureteral catheterization may be needed in establishing or excluding renal stone.

The pain of *renal colic* may be difficult to diagnose during an attack from gall-stone colic, lead colic, or appendicitis, but it begins below the lower ribs and has a characteristic tendency to pass downwards towards the umbilicus and thence into the groin. It may be attended by vomiting and fever. During or after the attack there may be blood and gravel in the urine; but it must be remembered that the urine may be heavily loaded with urates after an attack of biliary colic.

Pyuria may also be the cause. The urine will then furnish diagnostic indications (see PYURIA, p. 715, and BACTERIURIA, p. 88); and the kidney may be felt to be enlarged on bimanual palpation. The patient is often a pregnant woman, is always a woman rather than a man, and the pain may begin acutely, starting in the loin and right hypochondrium and passing downwards towards the iliac fossa and pelvis. There is pyuria, rigidity of the muscles, and hyperæsthesia both in the loin and in the right side of the abdomen.

A *Perinephric Abscess* may cause pain in the right hypochondrium and lumbar region. A tumour will be felt, the loin may be filled out, and there will be the usual signs of deep-seated suppuration.

Appendix. The pain of chronic appendicitis may be felt chiefly in the right hypochondrium, and may be of the nature of a hunger-pain. Tenderness over McBurney's point should be looked for. When an acute attack of appendicitis simulates gall-stones it may be of help to remember that indicanuria is common in the former, but is usually absent in the latter.

Colon. *New growths* in the neighbourhood of the hepatic flexure may cause pain

in the right hypochondrium : but in that case a tumour can usually be felt, and signs of chronic intestinal obstruction are present.

Uterine Appendages. *Salpingitis*, a *twisted ovarian pedicle*, and a *ruptured extra-uterine gestation* may all cause pain in the right side of the abdomen, which, however, has usually its maximum intensity rather below the hypochondriac region. A careful pelvic examination will usually make the diagnosis clear.

Pleurisy, Intercostal Neuralgia, and Herpes Zoster may be causes of pain in the right hypochondrium.

Subdiaphragmatic Abscess. In this case there will be a history pointing to precedent gastric or duodenal ulcer, appendicitis, hepatic abscess, or some operation upon the lower abdomen. The onset of the pain may be sudden or gradual. There will be pyrexia and leucocytosis pointing to deep-seated suppuration. The abnormal physical signs are generally few, but those that can be made out usually point to trouble down at the base of the right lung. The note over this may be tympanitic, from the presence of gas in the abscess, and in that event the coin-sound will be obtained on percussion. There are usually indications of pleurisy at the base of the lung, but the liver is *not*, as a rule, pushed down. The use of the X rays may help in locating the abscess : but the exploring needle should not be used except when the patient is on the operating-table and one is prepared to open the abscess at once if found. *Robert Hutchison.*

PAIN IN THE ILIAC FOSSA (LEFT). Although many of the causes of pain complained of mainly or entirely in the left iliac fossa are the same as those which cause similar pain in the right iliac fossa, there are certain differences, as will be seen on comparing the table on pp. 557-8 with the following : -

CAUSES OF PAIN IN THE LEFT ILIAC FOSSA.

1. Causes of Acute Pain :—

Acute diverticulitis	Oöphoritis	Local injury
Ureteral calculus	Pelvic abscess	Stitch
Acute ureteritis	Retained left testis	Volvulus of the sigmoid colon
Coli bacilluria	Suppurative periostitis of the ilium	Strangulated retroperitoneal hernia.
Twisted left ovarian cyst pedicle	Appendicitis (in exceptional cases)	
Salpingitis		

2. Causes of Subacute, Chronic, or Recurrent Pain :

Most of the conditions mentioned under Group 1	Psoas abscess	Periproctal abscess
Carcinoma of the sigmoid colon	Sacro-iliac joint disease	Periprostatic abscess
Carcinoma recti	Tuberculous hip	Dysentery
Massive impaction of feces	Osteo-arthritis of the spine	Ulcerative colitis
Chronic diverticulitis	Infective arthritis of the lumbar spine	Aneurysm of the left iliac artery
Spastic constipation	Herpes zoster	Sarcoma, osteoma, or other tumour of the left iliac bone
	Inflamed iliac glands	Tuberculous left kidney.
	Tuberculous iliac glands	

1. Acute Lesions.—What is said on p. 557, et seq., in regard to *ureteral calculus*, *acute ureteritis*, *twisted ovarian cyst pedicle*, *salpingitis*, *oöphoritis*, *pelvic abscess*, *retained testis*, *suppurative periostitis of the ilium*, *injury*, and *stitch*, applies in the case of the left iliac fossa as it does to the right, so that here we need discuss only *acute diverticulitis*, *appendicitis*, *coli bacilluria*, *volvulus of the sigmoid*, and *strangulated retroperitoneal hernia*. Of these, the last two call for immediate operation on account of urgent symptoms of intestinal obstruction, especially persistent constipation and vomiting, which becomes feculent if operative measures are not adopted soon. The precise nature of the obstruction may not be certain until the abdomen has been opened. Abdominal distention is apt to be general, and there is visible peristalsis of the oblique or transverse type in the case of strangulated retroperitoneal hernia, a rare condition in which a coil of small intestine becomes herniated through the normally small retrosigmoid pouch of peritoneum : whereas in the case of sigmoid volvulus the distention is at first much more marked in the left iliac

fossa before general colonic dilatation with vertical peristaltic waves appears. In either case the abdominal wall remains supple as a rule until, if the case should be left unoperated upon, general peritonitis supervenes.

Coli bacilluria is much less commonly a cause of pain in the left iliac fossa than it is of corresponding pain on the right side (p. 559); and when it does cause left-sided pain it nearly always causes an even worse pain on the right side also. It is a clinical fact that coli bacilluria affects the right kidney and ureter very much more commonly than the left, especially perhaps in pregnant women, in whom its incidence on the right side first or solely is an almost constant rule: why this should be so is not clear, although various theories have been put forward to account for it.

Appendicitis is perhaps almost the last thing that occurs to one as the cause of acute pain referred entirely to the left iliac fossa, just as it is the first thing in one's mind when the pains are on the right side; but it should not be omitted altogether from consideration: first, because in some cases, in which the vermiform appendix is very long, and inflammation starts at its tip and spreads to the left, as it sometimes does, the symptoms and even the swelling may be to the left of the middle line instead of in the right iliac fossa as usual; secondly, because in a few cases pains produced on one side of the body are referred to the corresponding region on the other side—for instance, some patients with a right renal calculus complain of pain in the left loin; and thirdly, because very occasionally one comes across a patient with transposition of the viscera in whom the caecum and vermiform appendix, and consequently their appendicitis, are on the left side.

Acute diverticulitis has been described as 'left-sided appendicitis', and this nickname is a good one in that, if one imagines acute appendicitis developing in the left iliac fossa, one has a very good idea of what the symptoms of acute diverticulitis and its degrees and results may be. In some it causes an acute abscess needing surgical measures for its cure; or there may be an acute attack without suppuration, spontaneous resolution occurring just as it often does in the case of acute appendicitis. The patient is seized almost suddenly with acute pain in the left iliac fossa, and generally vomits. It hurts him to walk, so he lies down or goes to bed. His temperature and pulse-rate rise, appetite fails, the tongue is coated, there is generally either diarrhoea or constipation, or the two may alternate. Micturition is often frequent because there is pain if the urine is held long; locally there are acute tenderness and pain, with rigidity of the muscles over the lower left quadrant of the abdomen, generally palpable fullness in the same region, and often an actual tumour difficult to define well; on rectal or vaginal examination pain may be complained of when the examining finger is pressed upwards and to the left. After a day or two these symptoms may begin to abate, and within a fortnight they may have disappeared; on the other hand they may increase rapidly and call for urgent surgical measures; or they may subside considerably without clearing up altogether, and may recur after a few weeks or months. At the operation the cause of the persistence of the symptoms will be found to be a local thick-walled abscess in the left side of the pelvis, strongly suggesting a pyosalpinx if the patient is a woman. General peritonitis may supervene at any stage, just as it may with any form of appendicitis. The cause of the disease, which is not so very uncommon though it is not always recognized, is the development of exaggerated sacculations of the colon with narrowing of their mucous-aspect orifices, so that if the interior of the intestine is seen it looks as if it had been punched with a series of small holes into which the end of the little finger may just pass, each such hole leading into a more or less dilated pouch or sacculus generally with an appendix epiploica attached to its free end: such a diverticulum seems liable to inflammation just as the vermiform appendix is, and the result is spoken of as acute diverticulitis. Long-continued constipation, together with chronic colitis, seem to be predisposing factors in the origin of these diverticula, and acute diverticulitis is a disease of the second half of life rather than the first. Either sex may be attacked.

2. Subacute or Chronic Lesions.—*Carcinoma* of the sigmoid colon or of the rectum may cause pain in the colon generally, owing to its distention with accumulated faeces; sometimes this pain is complained of chiefly over the descending colon, and thus in the left iliac fossa. As a rule increasing constipation will be a more prominent symptom, or alternatively a constantly repeated desire and necessity to defaecate without satisfaction in the result. If blood and mucus are passed per rectum, if the patient is over forty, has

had no bowel symptoms at all until the last two or three months, and has been losing weight, the carcinoma and its locality will suggest themselves at once, and an actual tumour may be felt in the left iliac fossa: the chief difficulty arises in cases who have long been habitually constipated so that it is difficult to assess the importance of the increased difficulty complained of. Rectal examination, the sigmoidoscope, X rays after a bismuth meal (*Fig. 140*, p. 161), or after a bismuth enema (*Fig. 141*, p. 162), may all be needed to exclude simpler conditions such as *impacted faeces* or *spastic constipation*, which are discussed under CONSTIPATION (p. 158).

Chronic diverticulitis (*Fig. 446*) is referred to under the heading of acute diverticulitis above: when it has given rise to a chronic thick-walled abscess in the left side of the pelvis it may produce symptoms very like those of carcinoma of the pelvic colon on the one hand, and of other forms of pelvic abscess on the other, especially pyosalpinx, or periproctal or periprostic abscess. Vaginal and rectal examination should be made, and then perhaps a primary source for one or other of these may be found: but not infrequently even when operative measures are resorted to a chronic diverticular or a chronic periproctal abscess and its resulting matting and thickening are mistaken for new growth, and the patient is regarded as having cancer unless his subsequent survival or alternatively a full post-mortem examination enables the diagnosis to be corrected.

All the other conditions mentioned in the table above are discussed in the article on PAIN IN THE ILIAC FOSSA (RIGHT), and what is said there applies as much to the left iliac fossa as to the right.

Herbert French.

PAIN IN THE ILIAC FOSSA (RIGHT). When a patient complains of pain in the right iliac fossa the first thing that occurs to one as the possible or probable diagnosis is appendicitis. As, however, there are a number of other conditions which may produce the same symptom it is important to consider the possibility of each before concluding that the patient really has appendicitis. The pains may be either acute and severe, or they may be subacute or chronic: they may be complained of by a patient now for the first time, or there may have been previous attacks. These characters, however, do not distinguish any one cause with certainty from the rest, though they may serve as a basis for classification as follows:

CAUSES OF PAIN IN THE RIGHT ILIAC FOSSA.

1. *Acute and Severe Pain:*

Acute appendicitis
Acute salpingitis
Acute distention of the caecum
with gas
Calculus impacted in right ureter
Acute ureteritis
Coli bacilluria
Twisted pedicle of right ovarian
cyst
Pelvic abscess

Retained right testis
Suppurative periostitis of
the ilium
Acute stitch
After local injury
Acute inflammation of the
iliac or ileocaecal lymph-
atic glands
Tuberculous iliac or ileo-
caecal lymphatic gland

Acute thrombosis of the
superficial circumflex
iliac vein
Acute destructive myositis
of the lower part of the
rectus abdominis muscle
Acute rupture of the lower
part of the rectus abdo-
minis muscle.

Fig. 446. Chronic diverticulitis. The descending colon after a bismuth meal, showing the contracted state of the colon and the multiple pellets of bismuth isolated in the series of colonic diverticula. The symptomatic cancer of the colon, but the X-ray appearances pointed to diverticula, and the latter condition was confirmed by operation.

2. *Subacute, Chronic, or Recurrent Pain :—*

Most of the conditions already enumerated in Group 1
 Ileocecal kink (Lane)
 Peri-appendicular adhesions
 Peri-caecal adhesions
 Psoas abscess
 Sacro-iliac joint disease
 Tuberculous hip
 Inflamed iliac lymphatic glands
 Tuberculous iliac lymphatic glands
 Tuberculous caecum
 Actinomycosis of the caecum

Carcinoma of the caecum
 Movable right kidney
 Tuberculous right kidney and ureter
 Intestinal obstruction at a point further on in the intestines, due to any cause, such as carcinoma of the sigmoid flexure, etc.
 Obturator hernia
 Herpes zoster
 Osteo-arthritis of the lumbar vertebrae

Infective arthritis of the lumbar vertebrae
 Dysentery
 Ulcerative colitis
 Typhoid fever
 Aneurysm of the right iliac artery
 Sarcoma, osteoma, or chondroma of the iliac bone
 Lobar pneumonia, pleurisy, or other chest conditions, with referred pain.

Formidable though the above list may seem, in the great majority of cases when a patient complains of pain in the right iliac fossa the first point to be decided if possible is whether that patient has appendicitis or not. In an acute case, in which the pains have come on rapidly and have become severe, associated with an increased pulse-rate, and some rise of temperature : vomiting at the beginning : a coated tongue : local rigidity over the right iliac fossa : perhaps with, in addition to a sense of resistance, a diffuse palpable fullness in the right iliac fossa, or even a more or less

localized tender swelling, together with tenderness of the right side of the rectum on rectal examination : the great probability will be that the patient has *acute appendicitis*, and in most instances surgical measures will be employed to cure the condition and at the same time verify the cause. The pain in cases of acute appendicitis is often associated with a remarkable localized acute tenderness referred to McBurney's spot, which is situated at the outer point of trisection of a line joining the umbilicus to the right anterior superior iliac spine : and there is generally acute hypersensitivity of the surface skin in the same region. Another sign which is sometimes helpful is congestion of the right superficial circumflex iliac vein : this may be obvious at a glance, and it is suggestive of active inflammation of the underlying appendix. As a general rule there will be some other abdominal symptoms as well pain in the epigastrium and vomiting, for instance : it is always dangerous to rely upon acute pain in the right iliac fossa

Fig. 447. Skigram of calculus impacted in the lower end of the right ureter. The diagnosis was confirmed at operation. (By Dr. C. Thurston Holland.)

alone in diagnosing appendicitis, and many a patient has been operated upon, appendicectomy being performed, when the real trouble has been in the right ureter, ovary, or tube, and not in the appendix at all.

Occasionally, when acute appendicitis has been the apparent diagnosis before operation, some other focal suppuration will be found when an operation is performed, a *pyosalpinx* or a *suppurating ovarian cyst*, for example : and it is generally at operation that *acute suppurative periostitis of the inner surface of the ilium* is discovered, a rare but important

condition which simulates acute appendicitis closely and is only to be cured by immediate surgical treatment.

A *ureteral calculus* generally becomes impacted in the lower end of the ureter close to the bladder (*Fig. 447*) : it sometimes gives rise to little pain : or it may produce acute ureteral colic, the pain being referred to the right iliac fossa in a way which simulates the pain of appendicitis closely : there may be local rigidity of the muscles, but no tumour can be felt, and as a rule the patient is much less ill than he is with appendicitis. In a first attack of such pain, however, an operation for supposed appendicitis may be performed : it is when the patient has had recurrent attacks, associated perhaps with transient hæmaturia, that the real cause is suggested, or more often still perhaps, the diagnosis is arrived at as the result of routine examination, including the use of the X rays, cystoscopy, and ureteral catheterization. The conditions likely to simulate a stone in the ureter when the X rays are employed are calcareous iliac glands or a phlebolith in formerly thrombosed iliac veins. It is often possible to tell the difference between these three by the relative situations of the shadows, especially if skiagrams are taken in different planes with an opaque bougie in the ureter.

Acute ureteritis produces symptoms almost exactly like those of an actual stone in the ureter. In some instances the inflammation of the lower end of the ureter results from a stone which has already passed : or it may arise as part of a *Bacillus coli* infection of the urinary passages, and in some such cases operation for supposed appendicitis has been performed, the vermiform appendix proving perfectly normal, but the ureter being seen to be thickened and inflamed. There can be no doubt that some such cases, diagnosed and operated upon for appendicitis, escape recognition altogether, for it is not always easy to tell whether the lower end of the ureter is inflamed when the tube is palpated from outside : the patient, at first regarded as cured by the surgical procedures, has the disappointment of suffering subsequently from precisely the same symptoms, periodically, as before the operation was done.

Coli bacilluria is a familiar difficulty in the differential diagnosis of appendicitis : although theoretically the pain should be referred mainly to the kidney, generally the right, it is quite common for patients suffering from this condition to refer their pain not to the back or loin at all, but to the front of the lower part of the abdomen, and particularly over the right iliac fossa, in such a way that acute appendicitis is simulated closely. Even though the urine be examined and a haze of albumin found, together with an excess of leucocytes, the acuteness of the condition may be such that the surgeon may not feel justified in waiting for cultures of a catheter specimen of the urine to be made to see whether the *Bacillus coli communis* is found : and not a few patients of this kind are unavoidably operated upon for acute appendicitis when the appendix is perfectly normal. *Coli bacilluria* is described on page 88, and *Fig. 448* is a temperature chart from a case in which appendicitis was simulated so closely that operation was performed and the diagnosis of coli infection of the right urinary passages including the kidney, confirmed by the surgeon.

Twisting of the pedicle of an ovarian cyst upon the right side generally produces symptoms analogous to those of strangulated hernia, and the diagnosis may only be established when urgent laparotomy is performed. As a rule the pain starts in the lower part of the abdomen before it becomes general, and in the case of a cyst upon the right side it may be referred particularly to the right iliac fossa, so that appendicitis may be simulated, especially as the patient may be very tender in the right lower quadrant of the abdomen, and a diffuse swelling may be felt here. Effusion of fluid into the general peritoneal cavity takes place rapidly so that there may be dullness in the flanks : the peritonitis which produces this is generally non-suppurative. The emergency is one which calls for urgent laparotomy, and the diagnosis is confirmed when the abdomen has been opened.

Acute salpingitis or *inflammation of the right ovary* is generally secondary to some other pelvic inflammation which has been diagnosed on account of other symptoms, such as a vaginal discharge (p. 231), pain in the pelvis (p. 572), or some menstrual irregularity such as menorrhagia (p. 482). The skilled gynecologist may, by vaginal palpation, be able to determine the cause, though doubts may exist as to whether the condition affects the right uterine appendages or the vermiform appendix, until laparotomy is performed.

Operation, as a rule, is less urgent in the case of salpingitis or ovaritis than with appendicitis. Should the pains in the right iliac fossa be relatively slight in the intermenstrual periods, but severe at the time of the periods themselves, this fact will suggest that the mischief is pelvic and not appendicular; but even this conclusion is open to fallacy, because when there has been preceding appendicitis with extensive adhesions which may very likely include the uterine appendages, the pains, though primarily the result of appendicitis, may be recurrently worse at each monthly period. An important point, however,

Fig. 118. Temperature chart (four-hourly) from a case of acute colic bacilluria. It shows one period of the acute trouble after an apyrexial interval.

is that salpingitis and ovaritis, though possibly unilateral, are much more commonly bilateral, so that the distribution of the pains is likely to be much wider in the case of ovarian or Fallopian tube mischief than it is with or after appendicitis.

Acute stitch generally affects the flank in the lower costal region on one side or the other, but sometimes the muscles over the right iliac fossa are involved instead of the abdominal muscles higher up or the diaphragm, and acute pain results in the right iliac fossa, and the patient may fear appendicitis. The general character of the pain, however, the fact that it appears to be definitely in the abdominal wall, and that it is unassociated with acute hyperæsthesia or with swelling or pyrexia, will generally serve to distinguish stitch from appendicitis.

Distention of the colon with fæces or with gas seldom produces very acute pain in the right iliac fossa, but rather a severe grumble; and although in a first attack appendicitis may be feared, recurrence of similar attacks without severe illness on the patient's part, and the way the pains are almost immediately relieved if the patient can pass flatus abundantly, or has his bowels evacuated, either naturally, by medicines, or by means of

an enema, will generally serve to exclude acute appendicitis at any rate, though doubt may remain as to whether there may not be appendicular or perityphlitic adhesions. In some such cases examination of the bowel with bismuth and the X rays may serve to show the distended condition of the cecum, or on the other hand evidence of deformity or immobility from adhesions.

Retention of the right testis is a thing which should not be forgotten, especially when a lad at about the time of puberty complains of acute pain in the right iliac fossa suggesting appendicitis. The testis, if it is situated at the upper end of the inguinal canal, may cause subacute pain similar to that of mild appendicitis, especially as at the same time there may be local resistance suggesting a swelling in the iliac fossa. It is important to examine the scrotum to see whether both testicles are present there or not. There is no pyrexia.

Injury to the right iliac fossa may be followed by acute pain. In most instances the history will indicate the diagnosis clearly, especially if there is local evidence of bruising. Sometimes, however, the patient may have injured himself when he was unaware of doing so, for instance during times of great excitement, or perhaps when he was under the influence of drink, or again, during a nocturnal attack of epilepsy, and it may then be very difficult sometimes to tell whether the pains are due to injury or not. The absence of pyrexia and of an increased pulse-rate will be points against acute appendicitis, though there may be local swelling from a deep hematoma, and the injured muscles may be rigid.

It is often forgotten that acute, subacute, or chronic *inflammation of the lymphatic glands* in the abdomen may cause pains as severe as those due to similar inflammation of glands in the neck, axilla, or groin: the glands at the ileocecal junction may become inflamed from various forms of microbic absorption from the colon and cause pains referred to McBurney's spot, simulating appendicitis so closely that operation is often performed and a normal appendix removed. The mistake is less likely to be made if there is tenderness in the left iliac fossa at the same time as the more acute trouble in the right.

Acute affections of the lower part of the rectus abdominis muscle may not be common, but they need bearing in mind: for when they occur on the right side they simulate appendicitis closely. Quite a number of such cases were met with during the last big epidemic of influenza: apparently the primary cause was thrombosis of the veins in this part of the abdominal wall, leading to acute necrosis of the lower part of the rectus muscle, with pain over the right iliac fossa, pyrexia, and local rigidity. The diagnosis is necessarily difficult, but it might be suggested by the contour of the parts locally, the distribution of the pain over a definite entire sector of the muscle, or by local subcutaneous discoloration. Appendicitis may similarly be suggested if rupture of the muscle in this district occurs when there has been Zenker's degeneration in it after such illnesses as typhoid fever. Quite often the operation for appendicitis is undertaken and the diagnosis made only after the muscle itself has been cut into.

Subacute or Chronic Lesions.—Passing on now to a consideration of the differential diagnosis of conditions which may produce subacute, chronic, or recurrent attacks of pain in the right iliac fossa, it is clear that most of the conditions described above need to be borne in mind again, though one need not recapitulate what has already been said in regard to them. Many, if not all, of the additional causes mentioned under the second heading, however, may simulate or be confused with subacute or recurrent appendicitis.

The *ileocecal kink* of Sir Arbuthnot Lane is familiar, though it is generally held to be far less common as a pathological state than Lane himself once thought: it leads to constipation by interfering with the free passage of the intestinal contents from the lower end of the ileum into the cecum, and as a result of this kink discomfort, or a dull grumbling pain, or even an occasional acute pain, may result in the right iliac fossa. It may be difficult to tell whether there is not appendicular trouble at the same time, but the diagnosis of the kink itself is relatively easy if a serial examination of the alimentary canal is made with the X rays after the administration of bismuth or barium. The actual narrow point between the bismuth kept in the lower end of the ileum beyond its proper time and the bismuth which has got past the kink into the cecum can generally be seen clearly. It is important when making the examination that the patient should have no paraffin, aperient or enema during the period of the successive X-ray examinations.

Adhesions round the appendix itself, or round the caecum, may be very difficult to diagnose unless the patient has recurrent pains in the iliac fossa subsequent to a preceding attack of appendicitis but without recurrence of signs of inflammation, pyrexia, or raised pulse-rate. In some such cases, however, it is only when operation is performed for the relief of the symptoms that the adhesions can be diagnosed with certainty.

Tuberculosis of the caecum is recognized nowadays more often than formerly (*Fig. 449*): it is nearly always associated with chronic phthisis, of which there will be either definite physical signs or X-ray shadows, and the sputum may contain tubercle bacilli. When the phthisis is active and extensive the number of bacilli swallowed are generally so numerous that if ulceration of the bowel occurs at all the ulcers are diffused widely through the ileum, caecum, and ascending colon; but even in such a case the post-mortem evidence

Fig. 449. Photograph of chronic tuberculosis of the lower end of the ileum, ileocaecal valve, and caecum successfully excised in a case of chronic phthisis with symptoms suggesting chronic appendicitis. The patient was alive and well seven years after the operation. *A*, Normal ileum; *B*, Dense tuberculous infiltration of the bowel wall; *C*, Ileocaecal valve, deformed by the tuberculous infiltration.

shows that the maximum incidence of the bowel tuberculosis which results from the swallowing of tuberculous sputum is in the region of the ileocaecal valve, presumably because some delay occurs here in the passage of the motions and gives the bacilli a better opportunity of attacking the mucous membrane. In cases which are less acute the bowel tuberculosis is sometimes confined entirely to the ileocaecal valve region, involving perhaps the last inch or two of the ileum, the ileocaecal valve itself, the caput caeci, and the first inch or two of the ascending colon. There may be diarrhoea as a result of this chronic ulceration, but as a rule there is none, and the patient has become so accustomed to his lung condition that he presents himself to the physician complaining of a sense of dull pain in the right iliac fossa with occa-

sional exacerbations. There may or may not be pyrexia owing to the phthisis. On examination an indeterminate fullness or even a definitely palpable mass may be felt in the right iliac fossa, and the first impression will probably be that the patient has chronic appendicitis, or even possibly carcinoma of the caecum. It is the concomitant lung trouble which gives the diagnosis, and possibly tubercle bacilli may also be detected in the faeces by the antiformin process. A certain number of these cases have now been cured of their bowel trouble completely by excision of the affected parts.

Actinomyces of the caecum is rare; when it does appear, it often baffles diagnosis. In some cases the nature of the mischief in the right iliac fossa is suggested by the fact that the patient has a chronic inflammatory, suppurative, or ulcerative condition either of the jaw or cheek (*Fig. 450*), or of the pleura and chest wall, or of the liver at the same time, for these, in addition to the caecum, are the sites most usually involved by actinomyces. The chronicity of the affection is generally pronounced, but the ultimate diagnosis depends upon the discovery of ray fungi from the affected part (*Fig. 610*, p. 779). Were the caecum involved primarily the symptoms would be more or less like those of either chronic appendicitis or of carcinoma of the caecum, and laparotomy would probably be resorted to, though if the nature of the malady were suspected large doses of iodide of potassium would be prescribed with or without actinomycotic vaccine treatment, cure possibly resulting without operation.

Inflamed iliac lymphatic glands may cause pain, tenderness, and obscure swelling in the right iliac fossa, and appendicitis may be simulated. There will generally be pyrexia; if the inflammation in the internal glands is due to spread from the femoral or inguinal glands there will generally be some sore place upon the skin in the area drained by the latter to indicate the diagnosis, but the inflammation of the iliac may occur independently of the inguinal lymphatic glands when the source of the infection is in the pelvis or secondary to periproctal or periprosthetic inflammation. Rectal examination will assist the diagnosis.

Tuberculous iliac lymphatic glands generally form part of *tabes mesenterica* or of tuberculous peritonitis (p. 64), but sometimes the tuberculous deposits occur mainly, or even solely, in the glands in the region of the caecum, in which case it may be very difficult to be sure without operation that the patient has not got chronic appendicitis or alternatively tuberculous lesions in the caecum itself (see above). It is only when one can feel multiple small but firm, tender swellings, as is sometimes possible in a thin person, that the diagnosis of tuberculosis of these glands may be guessed at: as a rule the patient is a child suffering from general delicacy, and the condition is not one in which the symptoms call for urgent laparotomy. Von Pirquet's skin reaction may be positive, though even when it is, the diagnosis of tuberculosis of these glands will often remain one of conjecture only. Sometimes the X rays show multiple shadows in the position which the glands normally occupy, and thus assist the diagnosis.

Carcinoma of the caecum is generally characterized much less by pain in the iliac fossa than by a definite, usually irregular, firm mass, at first movable, later more fixed. This

FIG. 149. Actinomycosis of the soft parts of the cheek and neck.
(From *Barchus' Die Chronik des Kopfes*, Julius Springer, Berlin.)

mass is distinguished from an accumulation of faeces in the caecum by its greater firmness, by the fact that it cannot be moulded by the fingers, and that it does not disappear when the bowels are thoroughly evacuated. It may enlarge very slowly: in cases of doubt, operation with a view to possible excision will probably be resorted to, and the diagnosis thus confirmed. Sometimes carcinoma of the caecum may be simulated by accumulated faeces, however, when there is obstruction to the bowel further on: there may for instance be adhesions obstructing the sigmoid colon, or a partial volvulus, or a carcinoma of the rectum, or of the sigmoid colon, leading to partial intestinal obstruction and preventing the faeces from leaving the caecum thoroughly even when evacuant measures have been employed. The pain which the patient then complains of may be not at the site of obstruction so much as in the right iliac fossa. A bismuth and X-ray examination may assist materially in detecting the cause of the symptoms in such a case, and careful examination of the rectum with the finger, or of the sigmoid colon by means of the sigmoidoscope,

may be required. It is noteworthy that when there is obstruction to the colon in its distal part, it is particularly in the caecum that *stercoral ulcers* are apt to occur, and these may be associated with perityphlitis and pain in the right iliac fossa, more or less simulating appendicitis.

As a great rarity a *hydatid cyst* may be found in the right iliac fossa, causing pain and a tumour simulating carcinoma even to the extent of producing obstructive symptoms. The diagnosis would seldom be possible without laparotomy.

In *dysentery* and *ulcerative colitis* the abdominal pains are usually general, or at least referred now to one, now to another part of the whole colon, so that in these conditions the patient seldom complains mainly of pain in the right iliac fossa; occasionally, however, pain in the right iliac fossa may be more pronounced than over other parts of the colon, though the diagnosis of a more widespread infection will generally be indicated by the history, especially as to residence in the tropics in the case of dysentery, or of recurrent intractable diarrhoea with the passage of blood and mucus in one suffering from ulcerative colitis.

In *typhoid fever* the general symptoms will nearly always be out of all proportion to any pain in the abdomen, but occasionally so mild a case of typhoid fever is met with—the ambulatory type—that the patient has not been ill enough even to go to bed, and in some of these acute pain in the right iliac fossa has been the first thing to call attention to the existence of disease; in some indeed the patient has had a perforation low down in the ileum, so that a local abscess has formed in the right iliac fossa, and the patient, though suffering from typhoid or paratyphoid fever, has been operated upon as an ordinary case of appendicitis until the subsequent course of the pyrexia has indicated that something else was wrong, and it has occurred to one to have the blood tested for a *Widal's* reaction which has then been found positive.

Discomfort or actual pain in the right iliac fossa may be the first complaint of patients suffering from a *tumour of the iliac bone*; this tumour may be simple *osteoma* or *chondroma*—or it may be malignant *sarcoma*. In either case the diagnosis is arrived at by careful deep palpation, when the tumour will be felt to be firm or even bony hard, and, unlike other tumours in the iliac fossa, completely fixed to the deep parts.

An *aneurysm of the iliac artery* is very uncommon: when it does occur, pain in the iliac fossa may be considerable, and this pain may radiate thence down the right thigh; the diagnosis would be made by careful palpation and the discovery of a tumour with expansile pulsation.

Although both *movable right kidney* and *other lesions of the right kidney*, especially *tuberculosis*, cause pain in the loin to a more pronounced extent than pain in the right iliac fossa, some patients, especially those suffering from unduly movable right kidney, complain of much more pain in the lower right abdominal quadrant than in the loin, and the difficulty of distinguishing between such pains, when due to movable kidney only, and a subacute appendicitis occurring in a person who has at the same time a movable kidney may sometimes be considerable. Careful urine examination should be made: with renal tuberculosis pus cells and tubercle bacilli may be detected; with movable kidney the urine is generally normal, though sometimes there may be a little albumin or occasionally a trace of blood. With movable kidney, however, there will be no pyrexia, such as one would expect were there also appendicitis, and on careful palpation the patient will tell the examiner that she experiences the pain when he has the kidney between his two hands and not when he presses into the right iliac fossa without touching the kidney. A difficult case may need cystoscopy, ureteral catheterization, and pyclography in both horizontal and vertical postures before the diagnosis can be made plain.

Herpes zoster is a condition which always needs bearing in mind when pains are unilateral without objective signs; herpetic pains may be present some time before the actual eruption appears, and also for weeks or months after the eruption has subsided. It is even probable that in some cases there are pains from herpes zoster without any eruption at all, though then the diagnosis is almost impossible. As a rule, with herpes zoster occurring in such a way as to produce pain referred to the right iliac fossa, the pain will not be confined to this fossa, but will be referred also to the inner side of the upper part of the thigh and to some point in the right loin, so that renal colic is more likely to be simulated than appendicitis. The characteristic vesicles will be looked for, or the slight scabs that may be left for some time after the vesicles have dried up.

The remaining conditions in the list above are those in which pain may be referred to the right iliac fossa from lesions at a distance, and it is only by bearing them in mind and looking for evidence of them that they can be recognized. Thus, the fact that a patient who is suffering from *acute pleurisy* at the base of the right lung, or from *pneumonia* in the lower lobe of the right lung, may complain of pain in the lower part of the abdomen rather than in the chest, is familiar; and sometimes it may be very difficult to decide whether the patient's lesion is abdominal or thoracic. Even when there are definite lung signs there may be doubt as to whether there may not be appendicitis as well; acute pleurisy, for example, may result from the rapid tracking up along the posterior abdominal wall of infection from the appendicular region. It is only by careful judgement that a decision can be come to. As a rule in such cases there is neither rigidity nor tenderness in the right iliac fossa upon examination, although the patient may put his hand over the right iliac fossa when indicating where he has the pain. In a similar way chronic pain suggestive of ureteral calculus or of appendicular colic or even a subacute appendicitis may be complained of by persons whose posterior nerve-roots on the right side are being irritated by bony or other changes in connection with the lower dorsal or upper lumbar vertebrae, for instance, from *spondylitis deformans* in an early stage; *osteoarthritis* of the spine; infective changes in the spine of the same nature as *rheumatoid arthritis*; *spinal caries* with or without *psoas abscess*. Such cases will be chronic, but the pains may be acute, and it may be only after much deliberation and repeated examinations that a conclusion will be come to that the pains are referred from the spine and not due to primary trouble in the right iliac fossa itself. The X rays will sometimes be of assistance in detecting the osteophytic or other bony changes in the vertebrae (Fig. 451), and yet absence of radiographic abnormality does not exclude infective spondylitis as the cause, for the inflammatory changes affecting the intercostal nerves as they emerge between the vertebrae may be confined entirely to the soft parts; if the patient's complaints can be analysed successfully it may be found that he has definite localized pain in the back as well as in the iliac fossa. The difficulty of being sure of the cause of the pains in such a case, however, may sometimes be very great, and even after weeks of observation their nature may still remain one of doubtful opinion only.

Herbert French.

FIG. 451. — Skiagraph showing tuberculous disease of 1st and 2nd lumbar vertebrae. (For lateral views see Fig. 482, p. 629, and Fig. 484, p. 630. (For Dr. C. Thorburn Halliday.)

PAIN, INTERSCAPULAR. (See also PAIN IN THE BACK, p. 526.) Pain referred to by the patient as being "in the back, between the shoulder blades", is due in the great majority of cases to simple indigestion, flatulence, or biliousness. Sometimes it is in the middle line, with a maximum intensity at the 5th, 6th, 7th, or 8th dorsal vertebra; sometimes it is referred more to one side of the mid-line than the other; often it varies in position, being sometimes near the mid-line, at other times right under the blade of one scapula—particularly on the left side in the case of indigestion and stomach conditions, on the right side when the patient is 'bilious' or his liver is out of order. It is very important, however, not to conclude forthwith that a patient who has this symptom is merely bilious or suffering from dyspepsia, for pain of a similar kind may be the result of more serious lesions, amongst which one must think of:—

Epithelioma of the œsophagus	Aortic aneurysm eroding the vertebrae
Mediastinal sarcoma	Gastric ulcer
Spinal caries	Duodenal ulcer
Sarcoma of the vertebrae	Gastric carcinoma
Carcinoma of the vertebrae	Gall-stones
Infective arthritis of the spine	Hepatic abscess
Fibrositis	Carcinoma of the gall-bladder
Myositis	Carcinoma of the liver.
Spondylitis deformans	

} 'Chronic
rheumatism'

The first step in arriving at a diagnosis will be to examine the bare back carefully by inspection in a good light, and by palpation. Broadly speaking, the conditions mentioned above divide themselves into two main groups—namely: (1) Those in which the pain is not produced locally, but is referred to the interscapular region from a distance (*Fig. 660*, p. 871); (2) Those in which the pain is definitely of local origin, so that there is tenderness on palpation as well as pain. When the pain is due to local causes there will generally be some deficiency in the free movement of the spinal column when the patient bends forwards and backwards or from side to side, or when he twists round; and attempts at such movements will increase the pain in a way which is not the case when the cause is gastric or hepatic.

Rigidity is most marked when the muscles or the bones themselves are involved, whether by *fibrositis*, *spinal caries*, *new growth*, *aneurysm*, *spondylitis deformans*, or *arthritis*. X-ray examination is essential, and a skiagram may yield the diagnosis forthwith; but absence of definite abnormality in the plate does not exclude local disease, especially fibrositis or arthritis; even new growths in the bodies of the vertebrae may escape detection with the X rays if a plate is taken in one plane only: it is important to take a plate of the bones in the left oblique position as well as antero-posteriorly (*Figs. 481-484*, pp. 629, 630). Skiagraphy will also serve to detect *mediastinal new growth*, or, with the help of a bismuth meal, *epithelioma of the œsophagus*, which is generally suggested by the progressive **DYSPHAGIA** (p. 240) long before it produces pain between the shoulders.

Infective arthritis of the spine, *fibrositis*, and *myositis* are all associated with local tenderness and local stiffness or deficiency in movement as well as with local pain: in only a few cases will the parts affected be the mid-dorsal region of the vertebral column alone; in most instances there will be pains in other parts of the body as well, referred to vaguely as 'neuritic', together with more or less affection of many joints of the multiple rheumatoid arthritis type (p. 426). All three are closely related to one another, and where fibrositis or myositis ends and infective arthritis begins is difficult to define. Local infiltration may sometimes be recognized on minute palpation, especially by those who have had training in massage. The diagnosis should not be made, however, before caries, aneurysm, and other serious deeper lesions have been excluded by skiagraphy.

When there is no local thickening, tenderness, or rigidity, and no local abnormality made out with the X rays, it will be probable that the interscapular pain, or the pain beneath the blade of one or other scapula, is a referred pain, either of gastric or hepatic origin. In many such cases the diagnosis of **FLATULENCE** (p. 302), or simple **INDIGESTION** (p. 395), or of biliousness is guessed at rather than made, and the chances are that the patient will be suffering from one or other of these ill-defined 'simple' conditions rather than from something more serious—such as gastric or duodenal ulcer, gastric carcinoma, gall-stones, hepatic abscess, or carcinoma of the liver or gall-bladder; especially if he has had similar pains on many previous occasions, losing them completely in the intervals. The severity of the scapular or interscapular pain is no guide, for it may be extreme even when the patient is suffering from nothing worse than flatulence or biliousness. It is important, however, not to jump too readily to the conclusion that the pain is due to these simple conditions, especially if it does not yield easily to simple treatment, such as bicarbonate of soda or a little calomel. Careful abdominal palpation is indicated, lest a gastric or hepatic tumour escape detection; with these the pain will seldom be solely interscapular, however, and here, just as in the case of gastric or duodenal ulcer, hepatic abscess, or gall-stones, there would be pain in the epigastrium or hypochondrium to direct attention to the nature of the lesion, which would be suggested further, perhaps, by such other symptoms as **VOMITING** (p. 927) or **JAUNDICE** (p. 405). Nevertheless, in some cases it may only be by watching the patient for a time that an exact

diagnosis can be made : and occasionally that which at first appears to be no more than the interseapular pain of dyspepsia or biliousness proves to have been really due to aneurysm, gall-stones, or a carcinoma.

Another condition apt to cause pain between the shoulders, or in a shoulder, or in almost any part of the back, is motoring, especially in an open car with the wind-screen so adjusted that there is a back-draught from behind, playing almost continuously on the shoulders and back when the car is going fast : persons who wear leather coats are less likely to be affected than are those who wear ordinary coats or wraps through which the back-draught can pass, chilling the dorsal tissues abnormally. The diagnosis depends upon inquiries as to motoring and upon the effects of re-arranging the wind-screen or the clothing or both if motoring is continued, or upon the benefits of stopping the use of an open car for a time.

Herbert French.

PAIN IN THE JAW (LOWER) unaccompanied by any swelling (see SWELLING OF THE JAW, LOWER, p. 834) is generally due to *dental caries*, i.e., toothache. The decayed tooth may be obvious at once, or it may be so hidden as to call for the services of a skilled dentist, assisted by radiograms of the jaw. Occasionally an unerupted molar may be the cause of the pain.

Neuralgia. Here, pain is the essential feature, and it may be of two kinds. It either follows the course of a nerve such as the inferior dental in the lower jaw, or it affects a considerable part of the jaw without special reference to any nerve. It varies greatly in severity, being sometimes slight, at other times so severe as to call for all the fortitude of the patient to bear it. Usually neuralgia of the inferior dental nerve is combined with neuralgia of the other branches of the fifth nerve (*tic douloureux*), and this in conjunction with the spasmodic character of the pain makes the diagnosis easy. Some cases of neuralgia are embarrassing, especially when sources of irritation in decayed teeth are present as well, and it may be that the true condition can be settled only after the paroxysms of pain persist after all the teeth have been extracted.

Other causes, such as epithelioma or other neoplasm, do not produce pain as a rule until the diagnosis has been arrived at on other grounds.

George E. Gask.

PAIN IN THE JAW (UPPER). What has been said above as to pain in the lower jaw being caused by dental caries and neuralgia applies equally to pain in the upper jaw, but there is an important additional cause to be sought for in the latter, and one easily overlooked, namely, inflammatory or neoplastic affections of the antrum of Highmore.

Abscess of the Antrum of Highmore. The presence of pus within the antrum is indicated by local pain, generally dull in character, but sometimes acute. On examination of the jaw the gums will often be found tender and swollen, and a carious tooth is frequently the source of the infection : it may for a time seem as if the pain is due to the septic tooth alone, without implication of the antrum, but implication of the latter will be suggested if there is tenderness on percussion over it externally, or if there is a periodical discharge of pus from the corresponding nostril when the head is bent forwards, or down the pharynx when the patient is lying on the back. If the normal opening of the antrum into the nose becomes closed, as it may from inflammation, this valuable symptom is lost, and though local signs of inflammation and general febrile disturbances are present it may be difficult to say whether the purulent trouble involves the antrum of Highmore or is due to inflammation in other nasal fossæ or to suppuration in the ethmoidal, sphenoidal, or frontal sinuses. A growth, innocent or malignant, starting in the antrum and not yet big enough to cause a swelling, may be mistaken for purely inflammatory trouble. Recourse should be had to the method of transillumination, and the antra on the two sides compared (see *Fig. 191*, p. 226). The position of the antrum should be shown by a bright red area, and if a shadow is thrown instead there is presumably some affection of the antrum. It does not mean necessarily that there is an abscess, for a growth or a thickening of the bone may cast a shadow equally well. In these conditions a skiagram may help. A growth may indicate its presence by pain before the appearance of any swelling, but the differential diagnosis is discussed under SWELLING OF THE JAW, LOWER (p. 834). The only certain method of diagnosis of an antral abscess is by tapping the antrum with an exploring syringe. This can be done through the nose immediately under the anterior part of the inferior

turbinate bone, or through a tooth socket in the upper jaw if there has been a previous extraction of a canine or premolar tooth. The fluid withdrawn may be subjected to microscopical and bacteriological examination. *George E. Gask.*

PAIN IN THE JOINTS.—(See JOINTS, AFFECTIONS OF THE, p. 423.)

PAIN IN THE LEG.—(See PAIN IN THE EXTREMITY, LOWER, p. 538.)

PAIN IN THE LIMBS (General).—In the majority of cases pains in the limbs are the result of some general or systemic disease: in but few instances can they result from symmetrically distributed local lesions. For clinical purposes they may be classified by their duration, according as they are acute or chronic.

1. Acute General Pains in the Limbs occur in—

Rheumatic fever	Hysteria	Inflammations of the
Muscular overstrain	Acute infections such as—	lungs, kidneys, etc.
Myositis—	Acute coryza	Secondary syphilis
Acute polymyositis	Tonsillitis	Tropical fevers
Neuromyositis	Febricula or chill	Dengue, Malta fever,
Trichinosis	Influenza	cholera, yellow fever,
Peripheral neuritis	Acute specific fevers	dysentery, malaria, etc.
Neurasthenia	Rat-bite fever	Trench fever

2. Chronic General Pains in the Limbs occur in—

Peripheral neuritis	Fibrositis	Cirrhosis of the liver
Tabes dorsalis	Rheumatoid arthritis	Bronchitis
Chronic rheumatism	Gonococcal arthritis	Morbus cordis
Myalgia	Gout	Malignant disease
Pernicious anæmia	Chronic wasting disease, as	Nephritis
Severe anæmia	pulmonary tuberculosis	Trench fever
Osteo-arthritis	Gastritis	

These general pains may be felt most acutely sometimes in one tissue or part of the limbs, sometimes in another. The muscles, for example, may be the chief seats of pain in a child with rheumatism: in a rheumatic adult the pains are usually worst in and about the joints: in a patient with secondary syphilis the pain is often deep in the bones, the so-called osteocopic pain. General limb-pains are usually made worse by movement, particularly when they are accompanied by inflammatory changes in the joints: but the general pains of chronic rheumatism, or the stiffness and pains left after muscular overstrain, will often pass off if the movements be persisted in for a little time. As a rule, general pains in the limbs are least felt when the patient is at rest, especially when he is at rest in bed: but in some cases rest leads to stiffness and increased discomfort, change of position giving temporary relief: in others—particularly the muscular pains of rheumatism and the osteocopic pains of specific disease—the pains are at their worst as soon as the patient gets warm in bed.

1. Acute Pain.—General pains in the limbs are common in *rheumatic fever*, occurring mainly in the limbs in which there is acute inflammation of the joints. In severe cases the cause will not readily be overlooked: it is in the comparatively mild cases in children that failure to make the proper diagnosis is likely to occur, when the general pains in the limbs may be set down as merely ‘growing pains’. There is no doubt that ‘growing pains’ occur in healthy children, quite independently of rheumatism: but any complaint of growing pains should lead to a careful investigation of the patient’s history, and of the condition of his heart: a family history or past personal history of either rheumatism or chorea will often be made out: and not rarely examination of the heart will lead to the discovery of valvular disease. The joint-affections of rheumatism are far more prominent in adults than in children: in children the non-arthritic lesions are the most conspicuous—endocarditis, pericarditis, pleurisy, chorea, inflammations of the fibrous tissues generally and of the skin, sore throats. The way in which both the pains and the pyrexia are relieved by salicylates may often assist the diagnosis: if both are relieved within forty-eight hours after salicylate treatment is begun, acute rheumatism is probable, whilst conversely, if the pains persist in spite of salicylates, acute rheumatism is not probable (*Fig. 329, p. 423*).

Few people can be unacquainted with the general pains and stiffness due to *muscular overstrain*, the result of some violent and unusual muscular exertion—walking, running, playing games, etc.—undertaken when the body is out of training. The pains are accompanied by local tenderness of the affected muscles, and there may be slight fever.

Myositis, or inflammation of the muscles, is a comparatively rare cause of general pain in the limbs. *Acute polymyositis*, also described as dermatomyositis and as pseudo-trichinosis, is characterized by pain, rigidity, and tenderness in the muscles, oedema of the extremities, and a rash resembling one or other of the exudative erythemas. In addition, there are the general symptoms of malaise, anorexia, general debility, and fever. It is sometimes due to generalized invasion by streptococci. It must be distinguished from trichinosis, in which the affected muscles are found to contain *Trichinella spiralis*, the face and eyes are oedematous, and the blood shows eosinophilia. A second rare form of myositis is the *neuromyositis* described by Senator, in which the nerves are involved as well as the muscles. In this, sensation is lessened, the reflexes are lost, and vasomotor phenomena are seen in the extremities. The affected limbs are tender on pressure, and painful when movement is attempted. (See also p. 501, and Figs. 559, 560). *Trichinosis*, or infection with *Trichinella spiralis*, is very rare in Great Britain, though common in countries where pork is eaten uncooked. Its symptoms are at first those of pyrexial gastro-enteritis, these being succeeded by acute pains and aches all over resulting from invasion of the tissues of the body, particularly the muscles, by embryo trichinellæ; the affected muscles swell, particularly the flexors. The face, neck, and trunk are affected as well as the limbs; the face and eyes become oedematous; profuse perspirations are common, and high fever is not rare; eosinophilia and leucocytosis are usual. If not fatal the symptoms last a month or more, subsiding gradually into the third stage, that of convalescence, as the larval trichinellæ become encysted in the muscles. The diagnosis of trichinosis is likely to be difficult because of its rarity; it is most likely to suggest itself when it occurs in epidemic form. In the early stages, acute gastro-enteritis, enteric fever, or even cholera, will be suspected, the main symptoms arising from the irritation of the alimentary canal set up by the parent trichinellæ breeding in it. Later, acute rheumatism will be simulated; but the pain and swelling are in the muscles, not the joints, and the occurrence of oedema and of eosinophilia should help in the diagnosis. It may be added that adult trichinellæ may be found in the stools of a patient with trichinosis, and larval trichinellæ in portions of the affected muscles removed *intra vitam* for microscopical examination (Fig. 452); encysted larvæ will also be seen in the infected meat that gave rise to the attack, should any of it have been preserved.

FIG. 452. *Trichinella spiralis* in human muscle. (× 400.) (Specimen kindly supplied by Lieut.-Col. Mac Arthur, R.A.M.C.)

Aching pains all over the limbs or body, or both, are quite common at the onset of many of the *acute infectious disorders*, or of acute diseases that mainly affect one or another of the organs of the body. Associated with these pains are other general symptoms, in most instances, such as malaise, headache, anorexia, and more or less fever. Thus, a severe *acute coryza* or *tonsillitis* may be ushered in by general pains in the limbs; so may the obscure and elusive acute attack known as a *febricula* or a *chill*, in which the fever and general symptoms persist for a day or two, but no localizing signs or symptoms can be detected to give evidence as to "where the chill has settled". Such febriculae may really be abortive attacks of pneumonia or rheumatism, the onset or recrudescence of pulmonary tuberculosis, instances of undetected sore throat, acute gastro-intestinal upsets, cases of larval enteric, scarlet fever, measles, or what not. If they are associated with much pain or prostration, there is a great tendency to apply the term 'influenza' to them indiscriminately, quite apart from considerations of fact—evidence of infection with Pfeiffer's bacillus; or of probability—the detection of any source whence influenzal infection could

have been derived. But, however satisfactory it may be to the patient, the diagnosis of *influenza* should not be made without further evidence, such as is furnished by the discovery of Pfeiffer's bacillus in the patient's nasal or bronchial secretions, or by the occurrence of the attack as one of many in an influenzal epidemic. Influenza is well known to be a protean disorder. In many instances its main symptom is a severe coryza, with headache, lachrymation, pyrexia, and much prostration. In others the type is respiratory; bronchitis with cough and viscid expectoration taking the place of the coryza, and leading up to a bronchopneumonia or lobar pneumonia that not infrequently results in death. A third variety of influenza is the abdominal and gastro-intestinal; abdominal pain, vomiting, diarrhoea, and perhaps jaundice, being the main phenomena. In all of these the pains, depression, and prostration come on very rapidly, and appear severe out of all proportion to the objective signs of the disease, while the fever is usually of short duration. The diagnosis of epidemic cases should not be difficult, but in the sporadic cases it may be far from easy, and must be made on the general lines indicated above.

It is not necessary to refer in detail to the many other acute infections or inflammatory processes in which general pains occur in the limbs. In *measles*, *scarlet fever*, or *small-pox*, for example, the pains often occur at the outset, but the diagnosis will be made on the other symptoms, and confirmed by the appearance of the characteristic rash. Recurrent attacks of high fever with pains in the limbs are characteristic of the little-known and rarely recognized *Rat-bite Fever* (see p. 740). Various febrile disorders of the lungs, such as *bronchitis*, *tuberculosis*, or *pleurisy*, may begin with similar pains; so may *gastro-intestinal* infections, or acute inflammations of the *kidneys*, especially *pyelitis* or acute *coli-bacilluria*. The diagnosis in these instances will be made from the special symptoms developed in each; the pains in the limbs will rarely be the only or the most prominent complaint.

In *peripheral neuritis* of the symmetrical multiple type, the amount of pain is very variable—great in some cases, little in others. The peripheral nerves contain motor, sensory, and vasomotor fibres; in peripheral neuritis, therefore, motor and vasomotor symptoms are habitually present, as well as sensory. Alcoholism is the commonest cause of multiple symmetrical peripheral neuritis; the chief complaints are of numbness and tingling in the extremities, 'pins and needles', sensations of 'dead fingers', cramps in the legs, and severe gnawing or aching pains in the limbs. Beginning in the hands and feet, they tend to spread to the trunk; motor weakness comes on, the skin develops hyperæsthesia, the limbs become very tender to pressure. The deep reflexes, originally increased, are now lost; the sphincters are hardly ever involved in alcoholic neuritis unless the mind is affected. Mental symptoms are common in alcoholism, taking the form of Korsakow's psychosis; memory for recent events is lost; the patient may forget his name and address, and not know where he is; and in the endeavour to make good the lacuna in his recollections, he is likely to tell lies freely, and quite without any definite wish to deceive. The

local signs of *arsenical neuritis* are similar to those of the alcoholic form, but incontinence and the cutaneous and deep hyperæsthesiæ are more marked, muscular paresis and wasting come on earlier, and there may be other arsenical symptoms (p. 83). In the neuritis due to acute *lead poisoning* the sensory signs are entirely subordinated to the motor, and pains in the limbs are absent. Peripheral neuritis is a fairly frequent legacy of *influenza*, and may then be characterized by great severity and persistence; it may also occur as a complication of other infectious disorders—such as diphtheria, tuberculosis, or syphilis. The diagnosis of peripheral neuritis will be suggested, speaking generally, if the pains in the limbs are associated with marked sensory changes—anaesthesia, paresthesia, hyperæsthesia—with tenderness of the skin, muscles, or along the course of the nerves, and with weakness, atrophy, diminished or absent knee-jerks and other tendon reflexes, and the reaction of degeneration in the muscles.

Hysterical and neurasthenic patients sometimes suffer acutely from pains in the limbs that lack any objective basis on examination, and may give rise to much trouble in diagnosis. It is of great importance that organic disease of every kind should be excluded before the diagnosis of hysteria or neurasthenia is given out. The hysterical patient is generally a woman, and is likely to exhibit several of the many phenomena common in hysteria, such as functional aphonia, globus or clavus hystericus, stocking-and-glove anaesthesia, hemianaesthesia, variable paralyses often due to the contraction of antagonistic muscle-groups, hysterical seizures, and the like. The signs and symptoms of hysteria

change from time to time, the recovery from any particular affection often being as sudden as its onset. The neurasthenic patient, on the other hand, is oftener a man than a woman, usually overworked, run down in general health, and worried. The symptoms are those of 'brain-fatigue' for the most part: inability to attend to or take interest in either work or pleasure; the bodily strength is lessened, and subjective sensations of all sorts may be felt in the back or limbs. Headache is a prominent feature in some neurasthenic patients; dyspepsia or palpitation in others; imaginary sexual disorders in others. Exaggerated knee-jerks accompany plantar reflexes that are still normally flexor, and the temperature is often subnormal.

General pains in the limbs are common in certain diseases of hot countries, of which only two need be considered here. Both occur in Southern Europe, as well as in more tropical regions.

Dengue is an epidemic infectious disease, much like influenza in many respects. Its onset is sudden, with headache and pains all over, fever, sore throat, sore tongue, an initial erythematous rash, rapid pulse, and frequent passage of frothing liquid stools. The pains may be in the joints mainly, or diffused throughout the muscles of the limbs, and are made worse by movement. After two or three days the patient feels better, and begins to get about again; but after an interval of a day or two a slight or severe relapse occurs, with pains as before, fever, and a secondary roseolar rash, which begins on the hands and wrists, later spreading in patches over the whole body. The relapse is soon over; but convalescence may be slow, with persistence of the general pains in the limbs. The diagnosis should be easy in epidemics of dengue; the sudden onset, extent of the pains in limbs, head, and loins, and the characteristic course, should suffice to distinguish sporadic cases from other acute disorders such as measles, scarlet fever, rheumatic fever, etc.

Malta fever occurs mainly in the Mediterranean and on its shores: it is a chronic fever (Fig. 547, p. 691), characterized by perspirations, constipation, and rheumatic pains in the limbs; arthritis, orchitis, and enlargement of the spleen are common. The early symptoms are obscure; but pains in the limbs and general debility, gastric derangements, headache, bronchitis, and continued fever, are the general characteristics when the disease is established. The diagnosis would turn on the discovery of exposure to infection, the milk of goats that are carriers of the *Micrococcus melitensis* being the actual vehicle of infection; the patient's serum shows the specific agglutinating reaction.

2. Chronic General Pains in the Limbs will often remain after several of the disorders mentioned under the former heading. Thus, the pains due to *peripheral neuritis* may become a chronic affection in cases of chronic alcohol, arsenic, or lead poisoning, after influenza, or in gouty, diabetic, or syphilitic patients. Usually only one or two of the limbs will be affected in these cases; and the diagnosis will not have to be made from the occurrence of the pains, but will have become evident from the development of other signs of disease: a blue line on the gums, tophi and previous attacks of acute gout, sugar in the urine, and so forth.

To certain uncommon cases of *tabes dorsalis* the name *tabes dolorosa* has been given, owing to the severity and extent of the pains. The patient presents the usual symptoms of *tabes* (p. 753); in addition he has frequently repeated lightning pains in the limbs, so severe as to form the dominating element in his disorder from the subjective point of view. The diagnosis will be made from the suddenness and shocking intensity of the pains on the one hand; and on the other, from the discovery of further signs of *tabes*—Argyll Robertson pupil, loss of knee-jerk and of ankle-jerk, ataxia, sphincter troubles, areas or zones of anaesthesia. The pains will have a radicular distribution, and the nerve-trunks and muscles will not be tender on pressure.

General pains in the limbs are common in *chronic rheumatism*, occurring particularly in consonance with changes in the weather. In some instances, the muscles are the chief seat of the pain; in others, the joints or the fibrous tissues round them; in others again, the nerves or the nerve-sheaths. Movement of the parts may be very painful, especially after a period of rest. The cause is generally a *fibrositis* resulting from microbe-toxin absorption from infected foci such as *pyorrhea alveolaris*, *apical dental infections*, *septic tonsils*, *infected nasal sinus*, *pyosalpinx*, *prostatitis*, *septic seminal vesicles*, *cholecystitis*, or *bowel infections*. Chronic rheumatism is seldom an inheritance from acute rheumatism, and is not frequently combined with valvular disease of the heart; it gives rise to

pseudo-ankylosis of the joints, inability to work, and much impairment of the general health. *Lumbago* and *sciatica* are probably but special varieties of similar fibrositis. The possibility of gonorrhœal arthritis, mis-called gonorrhœal rheumatism, must not be overlooked.

Myalgia, or the so-called 'muscular rheumatism', is a common affection of certain groups of muscles, and may in some instances affect the limbs generally. This, again, is but a variety of fibrositis, with causes similar to those indicated above for chronic rheumatism. It may be brought on acutely, however, by definite exposure to chill, exposure to cold after sweating, sitting in a draught, driving in motor cars, and the like. Its commoner forms, such as lumbago, stiff neck, pleurodynia, stiff back, need only be mentioned: in the rare cases where the limbs are attacked, the diagnosis of muscular rheumatism will probably be made *faute de mieux*, although there is nothing to show that the affection is rheumatic, and no proof that it is the muscles (and not their sensory nerves, for example) that are affected primarily. A particular variety, with a particular tendency to cause pains in the back and pains in the tibial regions of the legs, was very common during the war when *trench fever* abounded; but this malady is fortunately rare in civil life: it results from infection from lice.

It happens occasionally that severe pains in the limbs, or pains all over the body, are felt by patients with *pernicious anemia*. In some instances these pains are associated with great tenderness of the bones of the limbs and trunk to pressure, which may be connected with the hypertrophic changes taking place in the marrow within them. Similar aches, pains, and tenderness may be found in any of the *severe anemias* or *leukemias*.

There remains for consideration the large class of diseases characterized by *chronic wasting* or *cachexia*, in which general pains in the limbs are often prominent. These pains are due to widely different causes in different instances. In some they may be due to nothing more than exaggerated muscular fatigue or overstrain: the debilitated patient has but little muscle, and that little is exhausted by exertions that would be trifling for a normal subject, so that the cachectic patient becomes the victim of general pains by the mere fact of being up and about. In other cases the pains are connected with peripheral neuritis, set up by the circulation of toxins in the patient's blood, though few or none of the other signs or symptoms of neuritis may be detected on investigation. In others, again, the pains seem to be connected with the occurrence of fever, being lessened or absent when the patient's temperature is normal. In the great majority of cases these pains are lessened by rest, or by any treatment that builds the patient up and increases his strength. Either the lungs, the heart, the liver, and gastro-intestinal system, or the kidneys, may be the organs primarily at fault, and bodily wasting and weakness will be among the main symptoms. In cases where the organic disease is deep-seated and out of reach there is danger lest the patient who is really seriously ill should be suspected of nothing more than functional disease and treated for such. Thus, patients with carcinoma of the stomach may be treated for hysterical vomiting or anorexia nervosa: the victim of a carcinoma or aneurysm invading the spinal canal may receive the treatment usually meted out to a malingerer. It is important, therefore, that the most thorough examination should be made, and deep-seated organic disease of every sort excluded as far as is possible, before the diagnosis of functional disease be made in a cachectic patient. This is all the more necessary because there is no doubt that purely functional disease of long standing may reduce nutrition or bodily strength to a very low ebb and create a suspicion of grave illness when none exists.

A. J. Jer-Blake.

PAIN IN THE NECK.—(See SORE THROAT, p. 757; and STIFF NECK, p. 794.)

PAIN IN THE PELVIS.—In practice, pelvic pain can usually be classified under four headings, namely: (1) *Deep-seated pain*; (2) *Superficial pain in the skin*; (3) *Spasmodic pain*; (4) *Backache or sacralgia*.

1. Deep-seated Pain is aching in character, continuous, and may be acute in onset, or may be chronic in duration. It is associated with tension in the pelvic organs, usually the result of overfilled vessels, or, in other words, of congestion. If the result of actual inflammation, i.e., congestion due to infection, it is acute, and very severe. It is elicited by pressure, and thereby made worse. In its worst form it is of peritoneal origin; but it may

be due to simple congestion of the uterus, tubes, or ovaries, without infection or evidence of actual inflammation. The presence of adhesions between the pelvic organs is an important factor in the differential diagnosis of this type of pain, making it abundantly clear that there has been a past peritoneal inflammation, and that the tension in the organs is the result of the binding and pressure of new fibrous tissue. Thus it may be caused by : —

Local peritonitis due to infection, recent or remote, caused by salpingo-oöphoritis, infection after labour or abortion, ovarian cyst with torsion of the pedicle, extra-uterine gestation, appendicitis.

Simple congestion, caused by retroversion and flexion of the uterus, prolapsed ovaries, sclerosed ovaries, hemorrhagic corpus luteum cyst, 'tarry' cysts of the ovary, endometritis.

2. Superficial Pain in the Skin.— This is elicited by pinching or touching the skin with the head or point of a pin. It is essentially a referred pain, and may radiate very widely over the abdominal area, down the groins, over the crest of the ilium, and down the thighs. The area on the skin in which referred pain is felt in connection with uterine, tubal, or ovarian disease is that to which the tenth dorsal nerve is distributed : and the area is that which is commonly known as the 'ovarian region'. It is not, however, ovarian only, and it is not even uterine and tubal only, but may be affected also by lesions of the kidney, ureter, gall-bladder, and some parts of the intestines. Consequently, referred pain in the skin in this so-called ovarian region cannot be taken to indicate disease of the generative organs at all, unless other lesions can be eliminated. The region of the tenth dorsal segment is simply a horizontal band spreading behind from the first to third lumbar spines, and extending round the body with its upper level in front at the umbilicus. All parts of the region are not necessarily affected equally, and there may be points of maximum intensity : one, notably, is midway between the umbilicus and anterior superior spine. This spot, especially on the left side, has often been taken erroneously to indicate pain due to ovarian inflammation. It is interesting to note that referred pain is commonly more marked on the left side of the body, the explanation of which is not quite clear. Referred pain in this segment may not be due to any local lesion at all, but may be a marked manifestation of hysteria in its graver forms. When extreme hyperæsthesia of this area on the left side is accompanied by anæsthesia of the skin of the legs and feet up to the level of the knees, with brisk knee-jerks and absence of the palate reflex, the diagnosis of hysteria is almost certain.

3. Spasmodic Pain in the pelvis is nearly always due to painful uterine contractions when it is of genital origin. The exception to this is the pain, certainly spasmodic in character, which occurs in connection with *tubal gestation*, as a rule in the few days which precede tubal abortion or rupture of the tube. In this case it is supposed to be due to contraction of the muscle-coats of the tube, but there is no real evidence that this is a fact. There can be no doubt that, even though a part of the pain is muscular, some of it at least must be due to peritoneal irritation. The only way to diagnose between this tubal pain and that due to uterine contractions is by a careful consideration of the history of the case, and the finding of a definite tubal swelling by the bimanual method. Even then the diagnosis is exceedingly difficult and often impossible. Spasmodic pain due to *uterine contractions* is caused by : The onset of abortion or labour ; deficient development of the uterine muscle in spasmodic dysmenorrhœa (p. 237) ; expulsion from the uterus of a growth such as a fibromyoma ; 'after-pains' following labour ; gauze packing of the uterus after operations.

The differential diagnosis of these conditions is fortunately easy : but a much greater difficulty is sometimes met with when spasmodic pain has to be diagnosed which is due to causes that may not be of genital origin at all. The possible *extraneous causes* of a spasmodic pain have already been outlined (see DYSMENORRHŒA, p. 237), and are : appendicitis, intestinal, renal, or hepatic colic, leaking gastric ulcer, ruptured tubal gestation, twisted ovarian pedicle, hæmorrhage into a Graafian follicle, rupture of an ovarian cyst or pyosalpinx, dyspepsia, and flatulent distention of the bowels.

4. Backache, or Sacralgia, is a very common symptom in all classes of pelvic disorders : and may be present at the same time as deep-seated pain and superficial skin tenderness. It is associated especially with chronic uterine congestion and endometritis, backward displacement of the uterus, downward displacement (prolapse), and impacted uterine or ovarian tumours. Sometimes the only lesion to be demonstrated is a chronic

cervical catarrh or a cervical erosion. It is a very difficult pain to explain in all cases ; but it is usually regarded as one referred to the roots of the actual nerves which supply the uterus, tubes, and ovaries. In cases of impacted tumours it is possible that the pain is due to actual pressure on the sacral nerves at their exit from the bone, in which case pain will also be felt down the inner side and backs of the thighs. In cases of *carcinoma of the cervix* backache is complained of, but is always associated with pain in the 'ovarian regions', inguinal region, and also radiating down the legs. It must not be forgotten that this form of backache is not necessarily of genital origin, but may be the result of many other lesions. Thus, it may be the result of some irritating urinary constituent, like excess of urates, oxalates, or phosphates ; also it may accompany a calculus in the ureter or some lesion of the renal pelvis. As a rule, in renal cases, the pain is situated rather higher up. Further, caries of the spine low down, growths of the spine, or of the spinal-cord membranes, may give rise to it. Inflammation of the sacro-iliac joint, rectal growths, hæmorrhoids, ulcers, and simple proctitis due to scybala, may be its originating cause. It is clear that a correct diagnosis in any case cannot be made without a complete examination of all these structures, combined with careful urinary analysis. *T. G. Stevens.*

PAIN IN THE PENIS is a symptom which occurs frequently in urinary surgery, not only in association with lesions of the penis or urethra, but also as a referred pain with disease of the prostate, bladder, or kidney. It is common to many diseases, so that in the diagnosis of any case due consideration must be given to the other symptoms accompanying it, without placing too much reliance on a single symptom which may point strongly to the urethra or bladder.

Penile pain may be present either during or immediately after micturition, or may be entirely independent of the act. It may be said generally that if pain is felt only during micturition there is some inflammatory lesion of the urethra or prostate ; whilst if it occurs immediately after the flow of the urine it suggests some lesion in the urinary bladder. On the other hand, pain may be present quite apart from micturition, due to various diseases of the penis, bladder, ureter, or kidney.

The term 'pain,' too, is a relative quantity, varying with the nervous susceptibility of the patient, for what is pain in one may be merely discomfort in another, so that the patient's account may have to be discounted to a certain extent by the clinician.

I. CAUSES OF PAIN IN THE PENIS EXPERIENCED DURING MICTURITION.

1. *Diseases of the Urethra*—

Acute inflammation, gonorrhœal or other
The passage of a calculus or the impaction
of the latter

Stricture of the urethra

Injury of the urethra

Foreign body in the urethra

Diseases of the Prostate—

Acute prostatitis

Prostatic abscess

Prostatic carcinoma

Prostatic calculus

3. *Diseases of the Bladder*

Acute cystitis

Vesical calculus

Villous papilloma

Pedunculated carcinoma.

Diseases of the Urethra.—The commonest cause of pain in the penis *during* micturition is acute inflammation of the urethra, usually gonorrhœal, but occasionally septic. In the earliest stages of an acute urethritis, before any marked urethral discharge is apparent, there is usually a sense of smarting or tingling in the terminal urethra, more marked as the discharge increases, when it is of a burning or scalding character. This pain during micturition within a few days of sexual connection is frequently the earliest symptom of urethral infection, whilst a purulent discharge from the urethra is usually present when the case comes under observation.

The *passage of a calculus* through the urethra causes a sharp, cutting pain along the urethra, the cause of which is apparent when the calculus is voided. Occasionally it may happen that micturition occurs in these cases in the dark, or that urine is not passed into a vessel, so that the calculus is not actually seen by the patient ; but if there is a history of previous renal descent of a stone or symptoms pointing to vesical calculus, the sharp urethral pain during micturition occurring upon one single occasion is significant of the passage of a calculus. A stone may, however, pass on to the urethra during micturition and become *arrested* at some narrowed portion of the canal, usually at the membranous

portion or at the distal end, when a sudden, sharp pain is felt in the urethra, and at the same time the flow of urine is partially or completely stopped before the bladder has been emptied, whilst further efforts to expel urine only result in a forceless stream. In these cases the presence of a stone should be suspected, and the whole length of the urethra examined by passing the finger along its course, when a stone may be actually felt, or the canal may be illuminated by an endoscope and the calculus seen.

Occasionally a calculus may remain in the urethra, becoming gradually enlarged in size and causing pain on micturition. These calculi usually lie in the dilated posterior urethra behind a stricture in the bulb.

Urethral stricture occasionally causes pain in the urethra during micturition, especially if the calibre is small, and if there is septic infection or ulceration of the urethral mucous membrane behind the stricture, but as a general rule stricture causes but little pain: gradually increasing difficulty in micturition, feeble stream, and dribbling of urine from the meatus after the stream has terminated, are common symptoms: the diagnosis will be confirmed readily by the obstruction offered to the passage of a full-sized bougie, or, better, by direct observation of the urethra through an endoscope.

Injury of the urethra may cause pain during micturition. The urethra may be injured by a fall on the perineum, by a kick or blow, or by the faulty or careless passage of instruments: it may also be injured or lacerated in association with a fracture of the pelvis. The urethra may be merely bruised, may be lacerated on one aspect, or may be completely ruptured. If the urethra is injured there is usually an appearance of blood at the external urinary meatus, together with a contusion in the perineum or along the course of the urethra, if the laceration is caused by direct injury. Any attempt at micturition causes pain in the penis, whilst urine may or may not be expelled from the meatus, depending upon the extent of the injury, or may be extravasated into the perineal or scrotal tissues. As a rule no difficulty will be experienced in the diagnosis, but in any suspected case the greatest care should be exercised in passing an instrument into the urethra.

A *foreign body* in the urethra may cause considerable pain. In some cases the history will be clear of a broken end of a catheter or bougie passed along the urethra, but in others, in weak-minded individuals, no history of the insertion of a body into the urethra will be vouchsafed. Direct endoscopic examination of the urethra distended with air will show the foreign body. In this way various articles have been found in the urethra, such as a wax taper, a seed of barley with its barb, a hair pin, a small shell, a nail, a glass tube used to contain hypodermic tablets.

Diseases of the Prostate. *Acute prostatitis* and *prostatic abscess* both give rise to pain during micturition in addition to increased frequency and difficulty during the act. Both are usually sequelae of an acute urethritis, and whereas an acute prostatitis is accompanied by a temperature raised to 100–101° F., a prostatic abscess causes the usual rise and fall common to septic processes. The diagnosis of the two conditions is made readily on careful rectal examination, when the acutely inflamed gland presents a much enlarged, smooth-surfaced prominence in the rectum: whilst if an abscess be present a softer area in the inflamed gland can usually be detected. An acute prostatitis may accompany a haematogenous bacterial urinary infection as distinct from a venereal urethritis.

Adenomatous enlargement of the prostate gives rise to no penile pain during micturition: neither does the prostate containing tuberculous deposits: but pain in the penis is present during micturition occasionally in cases of *prostatic carcinoma*, owing to the direct infiltration of the urethral mucous membrane. Prostatic carcinoma is by no means uncommon, and whilst in its general symptoms it resembles those of prostatic adenoma, there is a marked difference found on digital examination of the gland per rectum. The carcinomatous gland presents rounded areas of densely infiltrated tissue, in contradistinction to the elastic, uniform feel of the adenomatous variety: the whole gland is fixed and immovable, and in advanced stages distinct infiltration of the lateral pelvic lymphatics may be felt extending laterally from the affected organ.

Care must be taken not to mistake the hard nodules felt in a prostate containing *calculi* for carcinoma. With calculous disease the gland is not fixed and is only slightly enlarged, whilst on gentle pressure with the examining finger the calculi may be felt to grate upon each other. During the passage of a catheter through the prostatic urethra distinct grating may be felt if any calculus has ulcerated the urethral wall.

Diseases of the Bladder may cause penile pain during micturition under certain circumstances, although it is much more common to find that pain in vesical disease follows the completion of micturition. In *acute cystitis*, penile pain is present throughout micturition, due to the intense congestion of the vesical mucous membrane of the trigone and around the internal urethral orifice. The other symptoms of acute cystitis, namely, suprapubic pain, pyrexia, increased frequency of micturition, and the presence of pus and blood in the urine, suggest the diagnosis.

Pain during micturition in other vesical lesions is caused whenever there is sudden obstruction to the normal flow of urine by the impaction of something against the internal urethral orifice. This may occur with a small *calculus* or with a *pedunculated tumour*, whether simple or malignant, when during micturition the flow is arrested suddenly, accompanied by a shooting pain in the urethra, whilst after an interval of a few seconds the stream may be re-established. With vesical calculus the urine may be normal or may contain pus and blood if the bladder has become infected: there is penile pain after micturition, and the stone may be felt with a sound. With a simple villous papilloma there is no pain unless part of the fimbriated portion of the tumour engages in the urethral orifice during micturition, but there are usually recurrent attacks of profuse hæmaturia, whilst with a villus-covered carcinoma there is increased frequency of micturition, with pain following the act, more or less constant hæmaturia, and usually pyuria. Upon rectal examination the base of the bladder may be felt to be infiltrated, but by far the most valuable means of diagnosis between the three conditions is cystoscopy, when a calculus or villous tumour is seen readily, whilst a pedunculated carcinoma appears as a dark red tumour covered with stunted processes. (See *Figs.* 288, 292, p. 354.)

II. PENILE PAIN FOLLOWING MICTURITION.

This symptom is common to many lesions of the urinary bladder, more especially those in which there is ulceration or infiltration of the basal areas. The particular pain felt by the patient is described as a sharp pricking or tingling at the terminal part of the penis on the cessation of micturition, lasting some minutes and causing a desire to squeeze the glans. It has often been described as typical of vesical calculus, but this is far from being the case, for it may be due to almost any affection of the trigone.

The common causes of pain in the penis following upon micturition are:—

Diseases of the Bladder.

A *calculus* in the bladder, unless it is trapped in the pouch behind an enlarged prostate or in a diverticulum, causes pain in the glans penis after micturition. It may exist without causing cystitis, although commonly there is some degree of pyuria when the case is first seen. There is increased frequency of micturition during active exercise or during the jolting of travelling, but not during complete rest unless cystitis is marked. The terminal drops of urine during micturition are often tinged with blood, and on some occasions there may have been a sudden stoppage of the stream during micturition. In some cases there is a history of the descent of a stone from the kidney without the subsequent appearance of a calculus in the urine. Patients subject to vesical stone have usually reached the later part of life, and although the symptoms are as a rule sufficiently marked to render the diagnosis easy, sometimes they may be so few that vesical calculus is quite unexpected, or the symptoms are so like those caused by other lesions of the bladder that error is easy. In such a case it is advisable to examine the interior of the bladder with a cystoscope rather than by the usual vesical sound; with a sound a small calculus, or one contained in a vesical pouch, may be missed, whilst with a cystoscope it is seen, its approximate

size determined, and any other condition of the bladder accompanying or simulating calculus may be diagnosed with certainty. (See *Fig.* 292, p. 354, and *Fig.* 294, p. 355.)

Vesical tuberculosis may be a primary affection, but is much more frequently secondary to tuberculous disease in some other part of the genito-urinary tract. It causes marked penile pain after micturition, together with pyuria and a tinge of blood in the terminal drops of urine; the frequency of micturition is increased during both day and night, and is uninfluenced by rest, thus differing from the increased frequency of calculous disease. Vesical tuberculosis usually occurs in young adults, but it must be distinguished carefully from other vesical infections, and more particularly from renal tuberculosis, in which symptoms referable to the bladder are commonly present before the bladder is attacked by disease. In a young patient in whom increased frequency of micturition, pyuria, and penile pain are present, a search should be made for any tuberculous focus, especially in the testes, prostate, and seminal vesicles, or for marked thickening of the terminal ureter as felt per rectum, whilst a careful search should be made for tubercle bacilli in the urine. A cystoscopic examination may be necessary to determine the extent of the disease (*Fig.* 574, p. 747), but, speaking generally, the less instrumentation that is carried out in these cases the better.

Vesical Tumours. Carcinoma of the bladder occurs in two forms: the infiltrating epithelioma and the villus-covered carcinoma. Either begins most commonly in the base of the bladder: the muscle becomes infiltrated so that contraction of the bladder during micturition causes pain referred to the terminal portion of the urethra. Both forms occur in elderly patients and give rise to increased frequency of micturition during both day and night, and to hæmaturia. They also often give rise to renal pain when the infiltration has extended to the ureteric orifice in the bladder. The base of the bladder may be felt per rectum to be infiltrated, or enlarged glands may be felt in the lateral pelvic space, and a cystoscopic examination will usually clear up the diagnosis (*Figs.* 288, 289, p. 354).

Whereas epitheliomatous growths of the bladder give rise to penile pain after micturition from the direct infiltration of the vesical walls, the pedunculated villus-covered carcinoma and the simple villous papilloma may give rise to sharp penile pain during micturition from blocking of the internal urethral orifice with a process of growth. The occurrence of this, together with attacks of profuse hæmaturia, are evidence of a pedunculated growth. On cystoscopic examination the carcinomatous pedunculated tumour is seen to be covered by blunt, stunted processes: it is often multiple, whereas the innocent villous papilloma is single and presents much more delicate fimbriae.

Acute cystitis causes tingling pain in the penis after micturition from the inflammatory infiltration of the trigonal area. The mode of onset, the character of the pain, and other symptoms of cystitis will point to the cause of the pain.

Bilharzia hematobia gives rise to clinical symptoms very similar to those of vesical tuberculosis. The history of residence in an infected district, microscopical examination of the urine for ova (*Fig.* 96, p. 102), and the typical cystoscopic appearance of the bladder (*Fig.* 291, p. 354) establish the diagnosis.

Ureteric Lesions not infrequently produce pain in the glans penis after micturition, and may cause considerable difficulty in the diagnosis from vesical disease.

When a *calculus* becomes impacted in the narrowed terminal or intramural portion of the ureter, symptoms are produced almost exactly similar to those of vesical calculus or tuberculosis, namely, increased frequency of micturition, pain in the glans penis after micturition, and a small amount of pus and blood in the urine. Intimate knowledge of the history of the illness will often be of value in these cases: the first attack of pain is usually described as being sudden, and felt in the renal angle posteriorly, passing forward above the iliac crest and spine, and finally becoming localized at the situation of the external abdominal ring. The calculus may become impacted in the terminal inch of the ureter, when, in addition to this pain, there will be increased frequency of micturition and penile pain, and possibly hæmaturia. With ureteric calculus there is usually pain in the kidney of the affected side from the dilatation of the pelvis of the latter. The diagnosis of these cases is not difficult if a careful inquiry is made into the history and symptoms, and so long as it is remembered that increased frequency of micturition and penile pain may be caused by ureteric impaction of a calculus; a good skiagraphic examination of the pelvic areas

may show the shadow of a stone (*Fig. 294*, p. 355), whilst the latter may be felt occasionally as a small, painful nodule above the seminal vesicles upon examination per rectum. A cystoscopic examination also affords valuable information, not only in excluding vesical lesions, but by giving a distinct indication of ureteric calculus by the marked congestion and dilatation of the blood-vessels in the immediate vicinity of the ureteric orifice. A small bougie passed into the ureter may meet with obstruction in its passage, whilst a wax-tipped bougie may be grooved or indented by the stone.

A stereoscopic radiogram of the pelvis with an opaque bougie passed into the ureter will show the shadow to be in the immediate line of the ureter (see *Fig. 362*, p. 443, and *Fig. 366*, p. 444).

Ureteritis descending from infection of the renal pelvis may give rise to slight penile pain and to increased frequency of micturition, and thus simulate vesical disease before the bladder is actually infected. This is seen most commonly in the *tuberculous* form, but is present in a less marked degree with infection by other organisms, of which the most common are the *Bacillus coli communis* and the *Staphylococcus*. In the non-tuberculous form, the ureter may be felt per rectum to be slightly thickened, but the cystoscopic appearance of the inflamed ureteric orifice is quite distinctive (*Fig. 572*, p. 717). In *descending tuberculosis* from the kidney, the ureter may be felt as a firm, infiltrated cord on the bladder base, the penile pain and increased frequency of micturition are more marked, the kidney may be felt enlarged and tender, and tubercle bacilli will be found in the urine. Apart from this, typical changes in the ureteric orifice are seen on cystoscopic examination, the orifice being pulled up or retracted or horse-shoe shape, and usually occupying a position slightly above and outside the situation of the normal orifice, due to the actual shortening of the ureter by infiltration of the submucous coats (*Fig. 573*, p. 717).

Diseases of the Prostate often cause pain in the penis immediately following micturition. This is seen most commonly with acute inflammation or abscess in the gland as a sequela of acute gonorrhoea or septic urethritis. In either case there is penile pain, sometimes associated with erection, but little difficulty will be experienced in the diagnosis on due consideration of the symptoms and upon rectal examination.

Prostatic calculi are not uncommon: there may be a single calculus or a nest of them in the prostate. They tend to ulcerate into the urethra so that small calculi may be passed in the urinary stream, or some may pass back along the dilated prostatic urethra into the bladder. If a calculus projects from the prostate into the urethra it causes pain in the penis after micturition. A diagnosis of prostatic calculus is often made by the grating sensation imparted to a catheter in traversing the prostatic urethra, whilst on rectal examination the calculus may be felt as an isolated, hard nodule in the gland, or, if more than one is present, by the crepitation of one upon another on digital pressure in the rectum.

Diseases of the Seminal Vesicle are seldom present without accompanying disease of the prostate or bladder. Acute vesiculitis may follow urethritis and give rise to pain in the penis after micturition, but in most cases it will be associated with prostatitis. Similarly tuberculous nodules in the vesicle will be associated with foci in the epididymis, prostate, or bladder.

Diseases of the Rectum and Anus may occasionally give rise to penile pain following micturition, apart from any infection of the bladder or prostate. Thus a carcinoma in the anal canal, a rectal fissure, or an inflamed hemorrhoid may occasionally cause pain in the penis, but in each the local symptoms of the trouble will be the more marked, and little difficulty will be found in the diagnosis if a local examination is made with care.

III. PAIN IN THE PENIS APART FROM MICTURITION.

Under the above divisions the symptom penile pain has been considered in relation to the act of micturition, and it remains to consider some conditions giving rise to pain in the penis *apart from urination*. These include certain local lesions of the penis and urethra, and also the pains referred from disease elsewhere. Although a local lesion may cause little more than discomfort in many patients, in some it is described as pain, the degree of which depends upon the nervous susceptibility of the individual. Thus penile pain may be present with *acute urethritis*, with *balanitis* in association with *phimosis*, with

paraphimosis, or with the *lymphangitis* of the organ due to a septic sore or abrasion of the skin or mucous membrane. In some instances *herpes* of the prepuce or penile skin causes distinct pain. Any infiltration of the cavernous tissue of the penis causes pain during erection of the organ: thus during an attack of acute urethritis the common symptom known as *chordee* arises from this cause, whilst, in a chronic form, *cavernitis* may be due to infiltration in association with tertiary syphilis or the gouty diathesis, so that erection of the organ is only partial or confined to the proximal part, and causes pain. Another condition causing the same trouble arises from the organization of a *hematoma* in the cavernous tissues of the penis following upon a local injury, either from external violence or during forcible attempts at coitus. A recent case of persistent erection without apparent cause under the writer's care was associated with severe penile pain; and a similar condition may be met with in blood diseases, especially *lymphatic* or *splénomédullary leucæmia*.

Epithelioma of the penis occasionally gives rise to pain in the organ.

Pain may be felt in the penis in some cases of *renal colic*, in which case it is classed as a referred pain. Thus in the acute colic accompanying the passage of a calculus, blood-clot, or debris of caseous material, aching pain may be felt in the penis quite apart from the increased desire to pass urine. Penile pain is, however, only a minor detail in the presence of the severe pain in the loin, and is often only lightly alluded to.

Pain in the penis was a prominent early symptom in two recent cases of *acute appendicitis* under the writer's care. In neither case was it associated with micturition, nor was there any increased frequency of micturition, but in both the appendix was found to occupy a very low position, turning down into the pelvis, which in one case contained a foul abscess.

R. H. Jocelyn Swan

PAIN IN THE PERINEUM is a symptom often mentioned by patients in giving their history of some affection of the genito-urinary apparatus or of other organs, but usually only as a dull aching, of which little notice is taken, as it is generally of minor degree in comparison with other more striking symptoms. The complaint of perineal pain *per se* does not convey much information to the clinician, and it is practically never present as the only symptom in a case.

Aching in the perineum is frequently present in diseases of the following organs:

<i>Prostate</i>	<i>Urethra</i>	
Acute or subacute inflammation	Gonorrhœa	Carbuncle
Abscess	Injury and rupture	Ulcér
Tuberculosis	Stricture with extravasation or urethral abscess	Carcinoma
Calculus	Fistula	<i>Vagina</i> -
Adenomatous enlargement	Calculus impacted in bulbo-prostatic portion	Acute inflammation
Carcinoma		Inflammation or abscess of Bartholin's glands
<i>Seminal Vesicles</i>		Cystocele
Acute inflammation	<i>Testicle</i>	Epithelioma
Tuberculosis	Congenital misplacement in perineum	<i>Cutaneous Diseases</i>
<i>Urinary Bladder</i>	<i>Anal Area</i>	Intertrigo
Cystitis	Hæmorrhoids	Eczema, gouty and diabetic
Tuberculosis	Fissure	Condylomata.
Calculus	Boil	
Carcinoma		

From the foregoing list it will be seen that aching in the perineum occurs with numerous different lesions, but other symptoms discussed elsewhere are in almost every case more marked.

R. H. Jocelyn Swan.

PAIN, PRECORDIAL. (See PAIN IN THE CHEST, p. 530.)

PAIN IN THE SHOULDER (see also PAIN IN THE EXTREMITY, UPPER, p. 543) may be due to two entirely different main groups of causes, namely: (1) *Direct causes*, in which the shoulder-joint itself is involved, or the nerves, ligaments, muscles, fasciæ, bursa, close to it; and (2) *Indirect causes*, in which the pains are referred to the shoulder region when the real seat of disease is at a distance, as in the case, for instance, of angina pectoris,

or gastric or hepatic or diaphragmatic disorders. The conditions to be thought of include the following :

1. Direct Causes : -

Injury	Neuritis	Reading in bed
Arthritis	Effects of exposure to cold	Subacromial bursitis
Synovitis	or damp	Muscular paralysis, local.
Fibrositis	Effects of occupations	
Myositis	Back-draught in motorists	

2. Indirect Causes :

a. Cardiovascular lesions—

Angina pectoris	Aortic atheroma (syphilitic)	Coronary artery disease.
Aortic valvular disease	Aortic aneurysm	

b. Pleural, pulmonary, or mediastinal lesions—

Pleurisy	Phthisis	Pneumothorax.
Pneumonia	Intrathoracic new growth	

c. Gastric lesions—

Flatulence	Gastritis, acute or chronic	Gastric carcinoma.
Indigestion	Gastric ulcer	

d. Duodenal lesions—

Catarrh, with or without jaundice	Duodenal ulcer.	
-----------------------------------	-----------------	--

e. Hepatic lesions—

Biliousness	Nutmeg liver	Hepatitis, acute, tropical
Gall-stones	New growth	Abscess.
Cholecystitis		

f. Pancreatic disease -

Chronic pancreatitis	Carcinoma of the pancreas	Cyst of the pancreas.
Stone in the pancreas		

g. Affections of the under surface of the diaphragm—

Local peritonitis from leaking gastric or duodenal ulcer or from hepatic abscess
Subdiaphragmatic abscess from whatever cause.

h. Nervous lesions—

Hemiplegia	Cervico-dorsal spinal caries	Pachymeningitis, syphilitic.
Herpes zoster	New growth in cervico-	cervico-dorsal
Acute brachiiitis	dorsal spine	Cervico-brachial neuralgia.

The term shoulder is not explicit, and patients may complain of pain in the shoulder when careful inquiry shows that it has widely different situations in different cases. In one it may be mainly in the root of the neck or in the central clavicular region ; in another the deltoid region in a second ; under the lower part of the blade of the scapula in a third ; and so on.

The first step in making the diagnosis is to locate the pain complained of as definitely as possible : it is often easy to diagnose its cause with some certainty from this point alone. If, for instance, the pain is mainly under the left shoulder-blade without any local tenderness at all, its origin is likely to be gastric or intrathoracic ; if mainly under the right shoulder-blade, duodenal or hepatic. (See PAIN, INTERSCAPULAR, p. 565.) If on the other hand the pain is definitely localized to the region of the shoulder-joint the mischief is probably within the joint itself, or in the fibrous tissues, ligaments, bursae, muscles, or nerves around the joint.

The next point to investigate is the condition of the parts at and round the shoulder ; if there is definite tenderness as well as pain, increased pain on attempted movement, local deformity from swelling or from wasting, or impaired mobility at the shoulder-joint, the trouble is probably local and the pains are not referred from the viscera. It may be difficult to be sure that there is no local tenderness as well as pain, for the patient may have suffered so much that he winces on palpation, from an expectancy of pain, when palpation or attempts at moving the joint are really painless ; considerable judgement

is required in deciding just how much tenderness is present as well as pain, especially in nervous subjects. If, however, there is definite tenderness as well as pain the trouble is most likely local, and the same applies when the pain is made materially worse by local movements.

In testing the mobility of the shoulder-joint it is important not to rely on the patient's statements or on inspection only; careful palpation is required. The patient may seem to move his shoulder well when, if the angle of the scapula is grasped whilst the patient moves his humerus, it will be found that the shoulder-blade moves synchronously with abduction of the arm, there being little or no play at the glenoid fossa. Normally, when the humerus is abducted the scapula should remain stationary until the arm is at a right angle with the trunk; if the upward movement of the extended and abducted arm is continued beyond the right angle, the scapula normally moves with it. If the scapula begins to move before the right angle is reached there is something the matter in or around the shoulder-joint. More often than not the mischief is due to peri-arthritis changes rather than to osteo-arthritis or intra-articular inflammation; part of the fixation may be due to the muscles being on guard to prevent movement that would produce pain in such cases, mobility becoming nearly perfect when the patient is anesthetized.

The differential diagnosis between the various conditions that may affect the joint is discussed in the article on JOINTS (p. 423). Fibrositis and myositis are in most respects equivalent to infective peri-arthritis, and it is often a matter of opinion whether any particular infective inflammatory condition around the joint is to be styled infective synovitis, or fibrositis, or neuritis, or myositis. Any of the four may involve one shoulder region only, but more often the patient has signs and symptoms of rheumatoid arthritis elsewhere also.

The effects of injury, exposure to cold and damp, and of occupations, when they involve the shoulder region, are only particular varieties of fibrositis, myositis, and arthritis. The stiffness and pain that may result from sleeping in a damp room with the shoulders uncovered by the bedclothes may be very severe, and they may take weeks or months to pass off. The chief question will be whether the exposure may not have caused actual rheumatoid arthritis, or have brought on a gouty inflammation or neuritis, in addition to mere stiffness and pain of a type allied to stiff neck or lumbago; and the differentiation will often be a matter of opinion. The same applies to the effects of injury: in some cases the bruising or the tearing of ligaments, or the fracture of bones, or their dislocation, may be followed by pain and stiffness continuing to affect the shoulder region for months or years afterwards; in addition, however, the injury may set up actual arthritis allied to osteo-arthritis, and, like the latter, more or less permanent. The X rays may help in determining the exact degree of local disease the injury has produced. Occupations involving constant use of the shoulder often result in permanent intra-articular changes also—a sort of osteo-arthritis: the tendency increases with age; and very likely the occupation—such as that of porters who carry heavy weights on the shoulder—determines the site of the first joint to be affected rather than actually initiates the disease. Besides intra-articular changes, however, occupations involving strenuous and constantly repeated use of the shoulders may cause pain in them of the same nature as that of writer's cramp and other occupation neuroses. Rowing men, navvies, stokers, and so on, may suffer in this way. It is often very difficult to distinguish between the occupation neurosis and organic fibrositis, myositis, neuritis, or arthritis.

One well-defined but often unrecognized cause of painful shoulder, in which both recurrent slight injury and occupation play an important part, is *subacromial bursitis* (see Fig. 338, p. 428). Outside the upper part of the capsule of the shoulder-joint, between it and the under surface of the acromion process, there is a fairly large bursa. This becomes inflamed from overuse or overstrain of the shoulder in much the same way as housemaid's knee results from persistent kneeling; but with this difference, that the swollen subacromial bursa cannot be seen or grasped as an inflamed prepatellar bursa can. Pain on using the shoulder in certain positions is the chief complaint. The trouble arises from falls or blows upon the apex of the shoulder, or from occupations involving repeated sudden jerks to the shoulders—it is common in golfers, tennis players, bowlers, or in those who throw the cricket ball or put the weight; it also arises when the daily work involves the maintenance of a strain against interrupted resistance, as in the case of

certain tools employed in electric steel grooving, electrical concrete-boring in the process of breaking up old roads, and the like. The diagnostic point is as follows: on minute palpation of the shoulder region, when the arm is at the patient's side there is a definitely and often acutely tender spot immediately below the tip of the acromion process, but if the patient now abducts the arm as far as he can, palpation of the previously tender spot no longer elicits any tenderness at all: on adducting the arm to the side the tender focus is again discoverable with ease. The explanation of the disappearance of the tenderness on abduction of the arm is that this movement takes the subacromial bursa far enough under cover of the acromion process for it to be no longer open to direct palpation. In cases of this sort examination by the X rays generally shows a wider clear space between the acromion process and the head of the humerus on the affected than on the normal side.

In any case of doubt, X-ray examination, not only of the shoulder region but also of the whole thorax, should be resorted to: now and again an unsuspected aneurysm of the

aortic arch interfering with the lower part of the right brachial plexus will be found to be the cause of acute pains in the right deltoid region: or a mediastinal new growth, or rarities such as a hydatid cyst in the chest (*Fig. 453*), may be discovered when mere arthritis has been suspected. *Angina pectoris* is responsible for very acute pain in the left shoulder region, but hardly ever here alone: the attacks, and the spread of the pain from the precordial region to the left shoulder and down the left arm, are generally characteristic: and their nature will be confirmed by examination of the heart, including resort to electro-cardiograms if need be, and by the influence of amyl nitrite or nitroglycerin on the paroxysms.

Pains referred to the shoulder in cases of *phthisis* are generally of the nature of dull discomfort or of aching rather than of acute pain, and the patient generally has had cough, wasting, night sweats and so on, to indicate the diagnosis, which is confirmed by the existence of abnormal apical signs, by the discovery of tubercle bacilli in the sputum, or by X-ray examination of

Fig. 453.—Skigram of a hydatid cyst of the lung: the position of the cyst is indicated by the arrow. The cyst lay behind and to the left of the heart. (By Dr. W. H. Coldwell.)

the chest (*Figs. 117-119*, pp. 133, 134). *Pleurisy*, *pneumonia*, and *pneumothorax* will hardly ever cause pain in the shoulder as their only symptom, and they will be diagnosed on other grounds.

Gastric, *hepatic*, and *duodenal* lesions causing pain in the shoulder do so in the subscapular region rather than in the region of the shoulder-joint itself—stomach disorders on the left side, hepatic and duodenal on the right. They are discussed in the article on PAIN, INTERSCAPULAR (p. 565)

Pancreatic lesions have to be thought of, and may be suggested by the fatty nature of the stools, by the pigmentary changes in the patient's skin, or by the occurrence of glycosuria; the further diagnosis depends upon somewhat elaborate and special tests which are described under CAMMIDGE'S PANCREATIC REACTION (p. 128).

A special variety of pain referred to the shoulder-joint region results from acute or subacute inflammation of the under surface of the diaphragm—so-called subdiaphragmatic pleurisy, which is not pleurisy at all but local inflammation of the peritoneum covering the diaphragm; if the front part of the under surface of the diaphragm becomes acutely

inflamed from any cause there is apt to be acute pain referred to the front of the shoulder-joint on the corresponding side ; if the centre of the diaphragm is affected most the pain is referred to the tip of the shoulder-joint region under the acromion process ; if the back of the diaphragm is involved the referred shoulder pain is posterior, under the hinder part of the deltoid muscle. It is sometimes possible, from these facts, to determine whether a subdiaphragmatic abscess is located more to the front or more to the back, and occasionally one finds the patient has complained much of acute pain in front of, or at the point of, or at the back of, one shoulder-joint suggesting acute synovitis when the actual cause is under the diaphragm : a leaking gastric ulcer, for instance ; or a perforated duodenal ulcer ; or a hepatic abscess with local peritonitis over it ; or spread of infection from a cholecystitis or a gall-stone state of affairs ; or appendicitis or perinephritis or pyosalpinx or other pelvic inflammation, with spread of the infection, not to the peritoneum generally, but up the back of the right side of the abdomen to the under surface of the diaphragm.

The chief difficulties that remain are the nervous causes, direct and indirect. *Herpes zoster* will be recognized by the characteristic eruption (p. 914), and the pains will nearly always extend down the arm and not be confined to the shoulder region ; but one needs to bear in mind that the pains resulting from herpes may persist for months after the eruption has disappeared, or may be severe before the vesicles come out ; perhaps the pains occur sometimes without any vesicular eruption at all, though the diagnosis of such a case could be but surmise. If there is local wasting of the muscles of the shoulder region it does not follow that the primary lesion is nervous, because precisely similar muscular atrophy results very rapidly from joint lesions ; with the latter, however, there is no reaction of degeneration (p. 724), whereas with true *neuritis* there is. It is, however, only when all intrathoracic lesions have been excluded, and when physical and X-ray examination point to there being no affection of the shoulder-joint, that neuritis of the circumflex nerve, for instance, should be diagnosed ; an inaccurate diagnosis of neuritis is so often made simply because the patient has pains and no apparent cause can be found to account for them. *Acute brachitis* is allied to acute sciatica and acute anterior cruritis ; it is diagnosed by analysing the distribution of the pains carefully, and by excluding gross lesions of other structures in the shoulder region or in the chest. It is often associated with marked muscular atrophy so that the humerus tends to fall away from the glenoid fossa and the patient uses a sling or splint for the better support of his arm. When there is no muscular wasting the same lesion would often be termed *cervico-brachial neuralgia*. Some such cases are due to much more serious lesions which may baffle diagnosis until the patient has been watched for weeks or months — *new growth* in the cervico-dorsal spine, for example, or cervico-dorsal *tuberculous caries*. X-ray examination of the vertebrae may assist in the earlier recognition of these conditions, but sometimes it is not until post-mortem examination is made that the exact cause of the pains possibly regarded previously as in the main neurotic is demonstrated ; suspicions would arise at once if the patient had had a cancerous growth removed at some previous date — amputation of a breast, for instance. The *hemiplegic* arm is sometimes the site of great pain, especially in the shoulder ; the pain is probably referred from the sensorimotor cortex of the cerebrum ; the differential diagnosis will be found in the article on HEMIPLEGIA (p. 381). Cervico-dorsal *pachymeningitis* of syphilitic origin may cause no more symptoms than ill-defined though acute pains in various parts of the neck, shoulder, arm, or hand ; peripheral neuritis or myofibrositis may be the diagnosis made. In most cases it is almost impossible to diagnose spinal pachymeningitis with certainty, though it may be guessed at if the Wassermann reaction is positive in blood or cerebrospinal fluid or both, especially if the cerebrospinal fluid also exhibits lymphocytes in excess ; the guess becomes more probable if the patient benefits from appropriate antisymphilitic treatment, though the converse is not equally true.

Reading in bed may be responsible for painful shoulder as a habit ailment. The attitude adopted often entails exposure of the right shoulder, and in cold weather the result in time is apt to be complaint of pains, sometimes intense and simulating neuralgia or rheumatism, interfering with movement, felt along the circumflex nerve and other branches of the brachial plexus, in the suprascapular triangle and at the insertions of the scapulo-humeral muscles, especially the deltoid. Muscular atrophy has resulted in some

cases : a particularly tender spot may be found just beneath the coracoid process, and another at the lower insertion of the deltoid muscle. The diagnosis may be suggested by inquiry as to bed-reading habits, and confirmed by finding that the pains presently cease if the habit is stopped, or if the shoulder is kept covered by a shawl. *Herbert French.*

PAIN IN THE SPINAL REGION. (See PAIN IN THE BACK, p. 526.)

PAIN IN THE STERNAL REGION. - (See PAIN IN THE CHEST, p. 530.)

PAIN IN THE TESTICLE of varying degree may be present in many conditions, which may be discussed under separate headings as follows : (I) *Diseases of the body of the testis or epididymis* ; (II) *Affections of the coverings of the testicle* ; (III) *Affections of the spermatic cord* ; (IV) *A retained or misplaced testicle* ; (V) *Pain from lesions remote from the testis.*

I. DISEASES OF THE BODY OF THE TESTIS OR EPIDIDYMIS.

Inflammatory Lesions may attack the testis proper, or, as is more common, may begin in the epididymis : they rarely remain confined to one part of the organ, however, for the process tends to spread rapidly from one part to the other, so that the whole organ is involved and the result termed an '*epididymo-orchitis*'. An inflammatory affection of the testicle may be acute, subacute, or chronic, the latter often being the terminal result of the former.

An acute epididymo-orchitis arises most commonly by spread of infection to the organ from the urethra via the vas deferens. When any inflammation has reached the prostatic portion of the urethra the orifices of the vasa deferentia may become infected, and inflammation spreads along the duct to the epididymis and testis. Whilst formerly the occurrence of an acute inflammatory condition of the testis, following upon some form of urethritis, was looked upon as 'metastatic', it has been shown that this view is no longer tenable, and that we must look upon it as a direct spread of infection via the vas deferens.

Causes of Acute Epididymo-orchitis :

Causes of urethral origin :

Gonorrhœal urethritis
Septic urethritis
Passage of catheters
Urethral instrumentation
Infection behind a stricture
Ulceration about an impacted calculus or
a prostatic calculus
Injections into the posterior urethra
After operations on the prostate

General causes : -

Fevers Parotitis (mumps)
Enteric
Scarlet fever
Injury
Influenza
Gout
Rheumatism
Hæmatogenous urinary affections.

epididymo-orchitis begins as a painful thickening of the epididymis associated with uride symptoms. Before any actual pain is noticed in the testis there is often a sense of discomfort and weight over the external abdominal ring and inguinal canal due to the inflammatory process extending along the vas deferens. The swelling of the epididymis increases, and with it the tubules of the testis proper become infected, causing swelling of its body and increase of pain. The whole organ thus becomes enlarged, and it is often exquisitely tender, the touch of the clothes or the most gentle examination causing pain. The swollen gland is often flattened on the outer and posterior aspect from pressure against the adductor muscles of the thigh ; the vas deferens and tissues of the spermatic cord are thickened.

By far the most common cause of an acute epididymo-orchitis is an *acute gonorrhœal urethritis*. During the third week of the disease the prostatic portion of the canal frequently becomes infected, when the orifices of the ejaculatory ducts may share in the inflammation, and infection be conveyed by the vas deferens to the testicle. Similarly, but less frequently, infection may arise from a *septic posterior urethritis*, contracted during connection with a woman the subject of a vaginal leucorrhœa. The gonorrhœal form of acute epididymo-orchitis usually resolves slowly, and shows very little liability to suppurate, whereas the inflammation resulting from a staphylococcal or a streptococcal infection may break down into a testicular abscess.

Acute epididymo-orchitis may also arise from septic processes in the urethra following the *passage of catheters, of instruments* for vesical operations, lithotripsy for example, from infection behind a *urethral stricture* or about a *calculus* in the prostatic urethra, occasionally after the *instillation of strong solutions* into the posterior urethra in the treatment of a chronic urethritis, or after operations on the prostate, especially prostatectomy. In any case the onset of pain and rapid swelling of the testis should lead to suspicion of urethral infection, and attention should be directed to the urethra with that in view. Bacteriological examination of any urethral discharge is essential (see DISCHARGE, URETHRAL, p. 227).

Acute epididymo-orchitis occasionally arises without any preceding urethral infection, and uncommonly occurs as a complication of *acute specific parotitis* (mumps), *enterica*, *scarlet fever*, *influenza*, or as a complication of a urinary infection by *Bacillus coli* or other organisms. The testicle becomes painful, and enlarges rapidly in the same manner as in acute inflammation from urethral infection, and under appropriate treatment gradually resolves. Less frequently testicular inflammation may occur with *gout* or *acute rheumatism*, or after a direct injury to the organ, such as a *blow* or *squeeze*, or from a fall astride a bar, or from partial torsion of a testis due to the effects of saddle-injury when riding.

The pain in an acute inflammation is generally of an aching character at first, felt not only in the testis but also at the external abdominal ring, and often as a heavy dragging pain in the loin of the affected side. As the testis enlarges the local pain becomes more severe, so that the swollen gland is exquisitely tender to pressure or to the touch. After a few days the pain subsides to a large extent, but remains as a dull ache until the swelling becomes greatly reduced, and it usually does not disappear entirely until the organ returns to the normal size. In a few cases in which a fibrous scar remains in the epididymis pain may remain and cause some difficulty in the diagnosis from a commencing tuberculous lesion, but the earlier history of acute inflammation will help in forming an opinion. In other cases the persistence of the pain and swelling may indicate the formation of an abscess in the testicle, when, after decrease at first, the swelling increases, the skin covering it becomes reddened, and a soft area becomes evident in one or other side of the organ.

Tuberculosis of the Testicle is comparatively common, occurring as a primary disease or secondary to tuberculous disease of the kidney, bladder, prostate, or seminal vesicles. It begins as a localized deposit in almost all cases, causing a rounded, firm nodule in the epididymis. It frequently arises in the upper pole of the epididymis, whereas the inflammatory affections secondary to urethral infection begin in the lower pole. This nodule may remain unaltered for many months, or may enlarge, soften, become adherent to the skin and coverings of the testicle, or actually ulcerate through them to form a discharging fistula in the scrotum. The small commencing nodule in the epididymis is usually painless at first and may be found by accident, but later, as it gradually enlarges, it causes an aching pain in the organ. Other nodules may be formed in the epididymis, or the body of the testis may become involved, whilst commonly small shot-like thickenings may be felt in the course of the vas deferens. In the most advanced stages, nodules may be felt upon rectal examination in the seminal vesicles or prostate, or there may be some in the epididymis of the other side.

Tuberculous disease of the testicle usually presents little difficulty in the diagnosis. In an early case the occurrence of one or more nodules in the epididymis, which are painful on pressure and which have not resulted from a preceding acute epididymo-orchitis, should always suggest a tuberculous focus, and a careful search should be made for other tuberculous lesions in the body. Should none be found one of the several clinical tests for tubercle, such as von Pirquet's tuberculin skin reaction, may clear up the diagnosis. In later stages the diagnosis is less difficult: the gradual enlargement of the nodules, their craggy or bossy feel, the infection of the vas or other genito-urinary organs with tuberculosis, and above all, the tendency of the focus in the epididymis to soften and to become adherent to the scrotal coverings and to produce an indolent sinus, are points to be looked for.

Syphilitic Disease of the Testis causes very little pain in the organ, but there is often a sense of dragging or heaviness. Syphilis may attack the testicle in several different ways, producing:

In Acquired Syphilis : -

Diffuse interstitial orchitis
Gummatous orchitis
Epididymitis

In Congenital Syphilis :

Interstitial orchitis
Gummatous orchitis.

The outstanding feature of syphilitic disease of the testicle is that it affects the body of the testis rather than the epididymis, thus differing in a marked degree from tuberculous disease. In the interstitial form there is thickening of the intertubular connective tissue, with an infiltration of spindle cells, which, forming young connective tissue, yield fibrous tissue when untreated. The subsequent contraction of this fibrous tissue may cause atrophy of the testis. The testis may, on section, show small gummata in addition to the diffuse orchitis, or if the inflammation is more localized, gummata may be the main feature, these varying in size from that of a pea to that of a walnut, or larger. The epididymis is affected but rarely, though cases are on record of a nodular swelling in the epididymis during the secondary stage of syphilis which disappears rapidly under anti-syphilitic treatment.

In congenital syphilis, both the interstitial and gummatous forms exist : they usually occur in childhood or in young adult life, and in many cases the affection is bilateral. Syphilitic inflammation of the testicle may be accompanied in either the acquired or the congenital form by a vaginal hydrocele.

There is a sense of weight in the scrotum rather than pain, and often an aching or dragging feeling in the inguinal or lumbar region. On palpation, the body of the testis feels enlarged and nodular with the gummatous deposits, but the epididymis can usually be distinguished from the testis and be found to be unaffected. The tissues of the cord remain unthickened. Tertiary syphilitic lesions of the testicle give rise to very little tenderness on palpation.

The diagnosis of syphilitic disease of the testis is usually simple. There may or may not be a history of syphilis, but other signs of the disease should be looked for : thus, in the acquired form, any scar of previous ulceration or periosteal thickening, or, in the congenital variety, signs in the teeth, eyes, or ears. If any doubt remains, a positive Wassermann reaction of the blood or the behaviour of the swelling when treated with large doses of potassium iodide and mercury, or salvarsan, should be noted, though it must be remembered that a gummatous testicle may not diminish in size with even vigorous anti-syphilitic treatment. Syphilitic disease is distinguished from *tuberculous disease* of the testis by the fact that the epididymis is usually free : that the cord, prostate, and vesicles remain normal ; and that pressure applied directly to the testicle gives little or no pain. Tuberculous deposits tend to soften and to involve the serotal coverings in spite of treatment. From *chronic orchitis* it is differentiated by the history of injury and by the absence of the history or signs of syphilis. From *malignant tumours of the testis* it is distinguished by the history of syphilis, the tendency of syphilitic disease to be bilateral, the slow growth, and a positive Wassermann reaction. In malignant disease, the increase in size of the testicle is more rapid, whilst the tumour often shows areas of varying consistency : the cord is often thickened in malignant or in tuberculous cases, but seldom in syphilitic.

Malignant Tumours of the Testis may give rise to pain in the organ, but as a rule pain is experienced only in the later stages of the disease. Both carcinoma and sarcoma may arise in the testis, but embryoma is more common, exhibiting both epithelial structures and a combination of several forms of connective-tissue type - cartilaginous, myxomatous, etc. Clinically, without microscopical examination, a soft carcinoma and a sarcoma can rarely be differentiated, and as their symptoms and history are so similar they may be considered together. A testicle that is the seat of a malignant growth enlarges rapidly, but as pain is at first absent there may be nothing to arouse the patient's suspicions. As long as the tunica albuginea remains intact the swelling retains the shape of the testis, but when perforation of the fibrous covering takes place nodular projections appear and render the tumour irregular. These projections are softer than the remainder of the growth, and form a valuable point in the diagnosis. A rapidly growing sarcoma or carcinoma of the testis may be so soft as to appear to be a fluid collection in the tunica vaginalis. Generally, however, although a growth may be accompanied by a small amount of fluid in the tunica vaginalis, the more solid mass can be felt through the fluid

on careful examination; this fluid is often bloodstained. The epididymis may become incorporated in the growth so that it cannot be distinguished, and the tissues of the cord become thickened. The coverings of the testis become stretched over the tumour: the mass does not become adherent to the scrotal skin until late in the disease. In both carcinoma and sarcoma, the iliac and lumbar glands become enlarged, and may be felt in a thin subject at the brim of the pelvis, and pain due to the pressure of these glands upon nerve structures may become marked. The inguinal glands are usually not enlarged unless the scrotal skin is affected. The diagnosis of malignant disease of the testis may be quite easy in the case of rapidly growing tumours, but in others, especially in the early stages, it may present great difficulty.

Between *sarcoma* and *carcinoma* it may be clinically impossible to distinguish. In quite early life the tumour is more likely to be a sarcoma: the cord is thickened earlier in carcinoma, but with rapidly growing tumours it may be quite impossible to say whether it is a sarcoma, carcinoma, or embryoma until a piece is examined under a microscope.

Orchitis may be confused with the more slowly-growing forms of sarcoma. In both the swelling may have followed an injury, and in both there may be a syphilitic history. Orchitis is, however, either more acute or more chronic, it retains more the oval shape of the testis, and does not present the rounded, slightly raised bosses which are commonly present in a sarcomatous testis. In orchitis the epididymis is usually distinguished more easily, and the cord is not so thickened as with a growth. Finally, the result of treatment with strapping and with mercury and iodide will often show the disease to be of a non-malignant nature.

Chronic torsion of the testicle is not very uncommon amongst habitual horse-riders, and sometimes, if there is no clear history as to the relationship between the swelling and a saddle-injury, the nature of the painful tumour may be so uncertain that operation and histological examination are resorted to.

Tuberculous disease is usually diagnosed easily from malignant disease by the tendency of tubercle to attack the epididymis, to caseate, suppurate, and to become adherent to the scrotal skin comparatively early. Tuberculosis occasionally attacks the body of the testicle first, however, forming an oval, smooth tumour of the organ: the epididymis and vas deferens may be unaffected for a time, and if no deposit is found in the prostate or vesicles, the differential diagnosis between tubercle and growth may be far from easy before operation. Tuberculosis most frequently occurs in young adults.

Hæmatocele. The diagnosis between a hæmatocele and a malignant tumour of the testis may present considerable difficulty. In both the swelling may date from an injury, whilst the indistinct fluctuation obtained in the soft areas of a growth, accompanied sometimes by some fluid in the tunica vaginalis, may simulate a hæmatocele. The latter feels heavy to the hand, but is usually softer in its whole mass and more regular than a growth. Care must be taken not to place too much reliance upon the withdrawal of a few drops of blood from the tumour by means of a trocar and cannula, a result which may happen equally with growth or hæmatocele. A hæmatocele may cease to enlarge, or even diminish in size, whereas, in growth, increase in size is progressive. The cord remains unaffected with hæmatocele, and testicular sensation is more likely to be lost in growth. If any doubt exist it is advisable to make an exploratory incision rather than a puncture, when, if necessary, a radical operation can be proceeded with.

Hydrocele. A hydrocele of very long standing, with an irregular, nodular surface, and absence of translucency due to the thickened tunica vaginalis and the thick contents of the sac, may simulate a new growth, but the long history of the case, and the absence of progressive increase in size of the swelling, will prevent a mistake of this kind.

Cysts of the Testis occur most frequently in connection with the epididymis, very rarely with the body of the testis. These cysts are quite different from hydrocele of the tunica vaginalis, and are often spoken of as encysted hydrocele of the epididymis or testis, or as a spermatocele, although all do not contain spermatozoa. They cause a swelling of varying degree in the scrotum, and usually an aching in the testicle, groin, or lumbar region. They may arise as retention cysts of the tubules of the epididymis or from one of the fetal remains which occur about the globus major of the epididymis, namely the organ of Giraldès, the hydatid of Morgagni, or the vas aberrans of Haller. These cysts are usually placed above and to the outer side of the testis, occasionally behind it. They

move with the organ, and can usually be distinguished from the latter by the test of translucency. Their increase in size is very slow, but they may cause aching pain in the testicle by pressure upon, or stretching of, the tissues of the epididymis. They can be distinguished from hydrocele of the tunica vaginalis by the position of the swelling relative to the testicle, and by the fact that the fluid contained in them is colourless or slightly opalescent from the contained spermatozoa (*Fig 454*), in distinction to the straw-coloured clear fluid of a vaginal hydrocele.

Fig. 454. Spermatozoa.

II. AFFECTIONS OF THE COVERINGS OF THE TESTIS CAUSING PAIN IN THE ORGAN.

The only common lesions of the coverings of the testis are *hydrocele* and *hematocele*; new growths of the testicular tunics are so rare as to render them surgical curiosities.

Hydrocele may occur occasionally as an acute affection accompanying an acute epididymo-orchitis, injury to the scrotum, or in the course of acute specific fevers such as small-pox, rheumatism, or mumps. Acute hydrocele has been described in conjunction with acute lesions of other serous membranes

multiple serositis or polyorrhomenitis. The more usual form of hydrocele is the chronic variety, which may be due to some disease of the testicle, but for which, in the majority of cases, no ascertainable cause can be found.

A hydrocele may cause some aching in the testicle, but more frequently it causes a dragging sensation in the loin from the mechanical effect of its weight. It forms a swelling on one side of the scrotum, oval with smooth uniform surface: it gives a distinct sense of fluctuation. The swelling is limited distinctly above from the cord or external abdominal ring, and gives no sense of impulse on coughing: with a good light it can be found in most cases to be translucent, the testicle occupying a posterior and low position in the swelling.

The diagnosis of hydrocele is usually easy, but difficulty may be experienced in old-standing cases in which the walls are much thickened. A hydrocele must be diagnosed from (1) A scrotal hernia, (2) Hematocele, (3) New growth, and (4) An encysted hydrocele of the testis.

Scrotal Hernia. Usually a hernia gives an impulse on coughing, can be reduced into the abdomen with a sudden slip or gurgle, and varies in size with the position of the patient. A hernia comes down from above and descends into the scrotum. In a large reducible hernia, some part of it is usually resonant from the contained intestine, the swelling is not limited above, and the testis can be distinguished at the bottom of the scrotum. A hydrocele is distinctly limited above, gives no impulse on coughing, is translucent, and the spermatic cord can be distinguished easily. The testis in a hydrocele cannot usually be distinguished in the scrotum as in a hernia. Difficulty may arise between the two conditions when the hydrocele extends along the inguinal canal and thus gives an impulse on coughing, or if the translucency is lost owing to the thickness of the walls or contents of the sac. A scrotal hernia in an infant may be translucent.

Hematocele is distinguished from hydrocele by the absence of translucency, the greater weight, and the suddenness of the onset, usually after an injury or puncture. If any doubt exist an incision may be made into the swelling, permission being obtained to proceed to any form of cure that may be found desirable.

New Growths of the Testis. A hydrocele is of much slower rate of increase in size, of smooth surface and uniform consistence, and is translucent.

Encysted Hydrocele of the Testis (see above).

Hematocele may occur as the result of tapping a hydrocele from puncture of a vein in the sac or of the testicle, or by the occurrence of bleeding into a hydrocele. It may

occur quite independently of a hydrocele, usually after direct injury. As a rule there is a rapid onset of swelling in the scrotum following the injury, with ecchymosis of the scrotal skin: the resulting tumour resembles a hydrocele in its clinical symptoms, save that it is not translucent. In other cases the swelling arises more slowly, when a pyriform or oval swelling is present in one side of the scrotum covered by normal skin: the surface of the swelling is smooth, and gives a sense of fluctuation and elasticity. There is no translucency, and, on tapping, dark blood-stained fluid is withdrawn.

The diagnosis in the less acute cases often presents a difficulty, especially with regard to *malignant disease of the testicle* (see above): from *hydrocele* it is distinguished by the absence of translucency: from *hernia* by the same points, except translucency, mentioned above in the diagnosis between hydrocele and hernia.

III. AFFECTIONS OF THE SPERMATIC CORD CAUSING TESTICULAR PAIN.

An inflammatory affection of the cord secondary to urethral infection is not uncommon. Tuberculous infection of the cord is practically never present without corresponding infection of the testis or epididymis. New growths of the cord, lipomata, myxolipomata, sarcomata, and hydroceles of the cord, cause no pain in the testis. A *varicocele*, especially if large, in a pendulous scrotum, is a frequent cause of a dull, aching pain in the testicle. The characteristic feel of the enlarged veins of the cord in the erect position, and the slight impulse on coughing, will readily point to the correct diagnosis.

IV. THE RETAINED OR MISPLACED TESTIS.

This, in its various situations, may give rise to pain, and many cause some difficulty in the diagnosis. A testis may be arrested in its descent at the external abdominal ring, in the inguinal canal, may remain inside the abdomen, or may pass into the perineum after traversing the inguinal canal, to the upper part of the thigh via the crural ring, or to the root of the penis in front of the pubes.

In the various situations in which an undescended or ectopic testicle is placed it may be attacked by the several diseases which affect the normally placed organ, and thus give rise to pain: but in addition, owing to the effect of recurrent muscular strains and the comparative immobility of the organ, it is particularly liable to attacks of inflammation, especially when the testis is retained in the inguinal canal: in the intra-abdominal position it remains protected from muscular injury, whilst ectopic testicles have a greater range of mobility than has one that is retained in the inguinal canal. The inflammation of an undescended testicle may be so acute as to lead to gangrene of the organ, with or without torsion of the cord. The pain may be complained of first when the testes begin to swell at puberty, at which time an undescended right testicle may produce symptoms easily mistakable for appendicitis.

The diagnosis of undescended testicle rests upon the following points: the fact that one side of the scrotum is empty: the outline and situation of the swelling in the inguinal canal or elsewhere: the testicular sensation upon pressure: and the recurrent attacks of pain. An undescended testicle may give rise to acute pain from inflammatory lesions or from acute torsion of the organ, and may, if it is in the inguinal canal, give rise to symptoms suggesting a strangulated hernia. A partially descended testicle is often accompanied by an inguinal hernia. It is also stated that the misplaced testis is prone to become the seat of malignant disease.

V. TESTICULAR PAIN FROM LESIONS OTHER THAN IN THE TESTICLE.

Complaint may be made of testicular pain when on clinical examination the testis is found to be normal. After an acute inflammation of the organ, even when no palpable nodule remains, the resulting cicatrization may cause aching in the organ, especially after *sexual excitement* or prolonged desire. Apart from former testicular disease pain may be felt in the organ if a *calculus* be present *in the pelvis of the kidney or upper ureter*, with a marked degree of *oxaluria*, or from stimulation of the peripheral nerves by *carcinoma of the bodies of the lumbar vertebra* or the pressure of an *aneurysm* in this situation. Pain in the testicle is occasionally present in *appendical inflammation* when the appendix turns down into the pelvis.

R. H. Jocelyn Swan.

PAIN IN THE THIGH. (See PAIN IN THE EXTREMITY, LOWER, p. 538.)

PAIN IN THE THROAT. (See SORE THROAT, p. 757.)

PAIN IN THE TONGUE. Pain in the tongue may be associated with some obvious and visible lesion, usually accompanied by breach of surface, such as an epithelioma, and conditions of this type are discussed under the heading of **ULCERATION OF THE TONGUE** (p. 895). On the other hand, pain in the tongue, or soreness of the tongue, may be a very real complaint when there is very little to be seen wrong. The conditions that have to be thought of then include the following :

1. When the Pain complained of is Not on the Dorsum, Tip, or Sides, but Underneath or Deeper:—

Injury to the frænum lingue	Foreign body in the tongue
Ranula	Periostitis of the hyoid bone
Calculus in the duct of a submaxillary salivary gland	Periostitis of the styloid process of the hyoid bone
Calculus in the duct of a sublingual salivary gland	Myositis
	Trichinosis.

2. When the Pain complained of Appears to be upon the Surface of the Tongue, even if it also Affects the Tongue as a Whole :

Bitten tongue	The effects of over-hot condiments such as cayenne pepper
After an anæsthetic (mouth-gag)	Neuralgia of the tongue
Injury by tooth or tooth-plate	Tie douloureux
Smoking	Chronic streptococcal glossitis
The effects of over-hot tea, potato, or other food	Epithelioma.

The differential diagnosis depends upon the following considerations :

1. When the Pain complained of is Not on the Dorsum, Tip, or Sides, but Underneath or Deeper.—

Injury to the frænum lingue may cause visible abrasion of the latter, or a definite ulcer, diagnosable at sight ; the most injured spot will be tender as well as painful, the diagnosis depending on careful attention being paid to the appearances and to the site of greatest tenderness. The cause may be injury by a fish-bone or other sharp or puncturing object ; or, perhaps more commonly, the effects of violent coughing bouts, as in whooping-cough, in which the protruded tongue may be forced against the lower incisor teeth with such violence that the frænum becomes abraded, inflamed, or ulcerated.

Ranula is not painful unless it is inflamed ; it is asymmetrical, forming a red smooth swelling in the floor of the mouth under the tongue on one or other side of the frænum ; its appearances are characteristic. It may result from obstruction of the duct of one of the sublingual salivary glands ; more often it is a retention cyst arising from one of the mucous glands in the floor of the mouth.

Calculus in the duct of either a sublingual or a submaxillary salivary gland may exist without pain ; or it may produce discomfort short of pain, or actual pain, recurrent or intermittent if there is no inflammation ; constant if there is. The stone may be very small and difficult to detect either with a probe or by the X rays (*Fig. 652*, p. 848), but its existence may be suggested by the situation of the discomfort, or by the way the corresponding salivary gland swells up when the patient begins to eat, the increased flow of saliva being unable to escape freely past the stone.

Foreign body in the tongue is uncommon, though a fish-bone may become impacted in it. More often the foreign body injures the tongue, escaping itself but leaving pain behind. The diagnosis depends on the accuracy of the story obtained, or on discovering the foreign body by palpation. A metallic or bony foreign body in the tongue would be demonstrated by the X rays.

Periostitis of the hyoid bone is less common than is *periostitis of its styloid process* ; each may cause pain in the root of the tongue, or far back and below the floor of the mouth, especially when the patient swallows. The pain depends upon the pulling the tongue movements give to the bone to which the lingual muscles are attached. Periostitis of the styloid process also gives rise to hawking and expectoration, and to a complaint of pain

deep down in the throat : it often leads to a fear of cancer, because the pain and discomfort are very certainly there and yet the doctor can see nothing wrong on any ordinary examination. The diagnosis may be suggested by the hawking, by the unilateral and constant situation of the pain, and by the fact that careful palpation elicits definite and sometimes acute tenderness precisely over the styloid process.

Myositis of the tongue is seldom if ever a localized condition : it may, however, be a prominent feature in *polymyositis acuta* (p. 701), though there are certain to be pains in various other muscles at the same time. The disease is very rare. So also is *trichinosis*, though in the latter the embryo *trichina* or *trichinella* seem to have a special predilection for the muscles at the base of the tongue, so that the latter becomes stiff, painful, and tender. The diagnosis will be extremely difficult unless there is an epidemic at the time, or unless the patient is known to have eaten pork that may have been infected. The blood will exhibit eosinophilia, but the only way of clinching the diagnosis is by demonstrating the trichina embryos (*Fig. 452*, p. 569) microscopically in portions of the muscles excised ; such diagnosis is generally made post mortem.

2. When the Pain Complained of Appears to be upon the Surface of the Tongue, even if it also Affects the Tongue as a Whole.

Bitten tongue may present an obvious lesion if the surface has been cut through : but a very painful place may remain after a tongue-bite even when no obvious bruising or breach of surface has been produced. The pain will be quite local, and the patient may be aware of having accidentally inflicted the bite : on the other hand, the accident may have occurred during sleep or during an epileptic seizure : the occurrence of a local painful area in the tongue suggesting the effect of tongue-bite may be the first indication that the patient is an epileptic.

After *anæsthetics* patients often complain of soreness of the tongue : the result of the use of tongue forceps or of a mouth-gag.

Injury by a tooth or tooth-plate may cause a local painful place upon one side of the tongue, often fairly far back, the pain being increased by movements of the tongue in speaking, eating, or swallowing, and even making free movement of the tongue difficult. The patient may have fear of cancer and be much alarmed until the cause is found in the jagged edge of the adjacent tooth, or of the filling in the tooth, or of the tooth-plate at the corresponding site. The condition needs to be watched carefully to see that the pain disappears soon after the offending irritant is smoothed down or removed, for until the pain is gone one cannot be absolutely certain that the jagged tooth or plate has not really started an epithelioma.

Smoking and the effects of tea or other *liquid or food taken into the mouth too hot* may cause acute local or general pain in the tongue lasting for days after the original cause has ceased to act : the diagnosis depends upon the history ; and the same applies to the effects of *hot condiments* such as capsicum, cayenne pepper, ginger, and the like.

Neuralgia of the tongue, tic douloureux, and *chronic streptococcal glossitis* may all be considered together, for one should never diagnose neuralgia or tic douloureux or neurosis of the tongue when constant pain in the tongue with little to see for it is the complaint, until every other possibility has been excluded. Many a case has been labelled a tongue neurosis or a tongue neuralgia unjustly when chronic streptococcal glossitis was the real and organic condition.

Sore tongue of this type is met with in cases of pernicious anemia sometimes, but it is commoner, and severer, in patients who may seem to be otherwise in good health. The pain and distress may be enough to drive the patient almost crazy, and yet the tongue may present little apparent abnormality to a superficial examination. At times the pain may be less, but it never goes completely : and it may last for years, rendering the patient's life a misery. If the tongue is watched over a period it will be found that sometimes parts of it become acutely reddened as though by local erysipelas, the reddening remaining in the same place for some days, but slowly extending to adjacent areas and passing from the part first reddened : or again, there may be a story on the patient's part that little ulcers come and go, though none may be visible when the tongue is seen ; or little cracks in the surface may develop ; or the surface of the tongue may exhibit fur of quite irregular distribution the geographical tongue (*Figs. 455-460*).

When the condition has lasted for months or years the tongue surface may look unduly smooth or glistening; or, again, if spread out by the fingers, it may be superficially cracked and fissured; yet none of these things may be obvious unless they are looked for carefully, and possibly repeatedly. Cultures from cracks or reddenings yield growths of *Streptococcus pyogenes longus*. The condition seems to be started by inoculation of these cocci into the

Fig. 455. Persistently painful tongue due to chronic streptococcal glossitis; the reddening of the margins, tip, and anterior third is typical of one phase of the malady.

Fig. 456. The same tongue as that illustrated in Fig. 455, but presented in lateral view to show the persistent marginal reddening.

Fig. 457. Chronic streptococcal glossitis (a painful "orange" tongue), exhibiting the irregular fissures which may not be apparent until they are opened by lateral stretching of the tongue.

Fig. 458. Another type of chronic streptococcal glossitis (a painful "orange" tongue), in which the area of infection is more definable than is the case in Fig. 455. Slowly, in the course of days or weeks, the area of infection spreads along the tongue, invading new areas, and healing in the parts it first involves.

tongue surface through some abrasion by a tooth or bite or fish-bone, but once inoculated they seem to persist just beneath the surface, worrying the nerve-endings, to the patient's distraction, in the same kind of way that streptococcal infection of the skin around the anus causes intractable pruritus and without much objective evidence of abnormality. The patient may be unable to drink hot tea or eat hot things, or spicy foods or things containing vinegar, ginger, or mustard; talking may become a nuisance because of the increased pain

tongue movements cause. Irritability and moroseness result, partly from the pain and discomfort, partly from the injustice of having the condition labelled neurotic or hysterical when it is real. Neuralgia or neurosis or *tic douloureux* of the tongue should never be diagnosed until it is certain that the diagnosis is not chronic streptococcal glossitis.

Fig. 439.—Streptococcal glossitis. The same case as Fig. 438, showing the appearance eight weeks later.

Fig. 440.—Chronic streptococcal glossitis. The same case as Figs. 438, 439, but on another occasion, after the tongue had seemed to get well and then began to be affected over again. This kind of thing kept on coming and going for many years.

Herbert French.

PAIN IN THE UMBILICAL REGION.

Pain associated with External Swelling. This may be due to the following causes:

Umbilical Hernia, common in infants, and in fat, middle-aged people, particularly women. Attention is often called to the protrusion first by the pain. In the early stages, while the hernia is yet small, it may be overlooked, especially if the patient is obese. The swelling is usually globular, has an impulse on coughing, and may or may not be reducible. In a large proportion of cases the hernia is irreducible, and it nearly always contains omentum.

Schacoccus Cyst, which is not uncommon at the umbilicus. It presents itself as a small spherical swelling, mistakable for a small irreducible umbilical hernia. There is, however, no direct impulse on coughing, and the swelling is attached to the skin. There is generally but little pain unless the cyst has become injured or inflamed.

New Growth. Occasionally the umbilicus is the seat of a small secondary nodule of growth which has been brought by the vessels in the round ligament from the neighbourhood of the liver. It may furnish a clue in making the diagnosis of an obscure intra-abdominal ailment. *Epithelioma* is the only likely primary growth here; it has to be distinguished from a mass of *simple granulation tissue*, and from *tuberculous ulceration of the skin* at the umbilicus; all three are uncommon; in some cases the diagnosis between them may be obvious almost at sight; in others the distinction may be so difficult that microscopical examination of a portion of the mass has to be resorted to.

Eczema Intertrigo. Obese people of uncleanly habits may suffer from this trouble at the umbilicus. It is diagnosed at sight.

Divarication of the Recti Muscles. A patient lying in the recumbent position may show no evidence of this condition. Diffuse pain is complained of about the umbilicus, and the divarication is made evident at once if the patient is asked to lift the head.

Cyst of the Omphalo-mesenteric Duct, a rare condition, may be found at birth.

Pain associated with Internal Swelling.

Tuberculous Peritonitis with formation of a localized abscess is the commonest cause of pain and a swelling situated inside the abdomen at the umbilicus. The patient is usually a child presenting signs of chronic abdominal disease.

Carcinoma of the Pylorus or *Carcinoma of the Colon* may cause a painful tumour in the

umbilical district of the abdomen : each is to be diagnosed from other symptoms arising in the case, assisted by bismuth and X-ray examination, X-ray examination after a bismuth enema, and by the results of test meals.

Pain without Swelling or other Localizing Symptoms.—The causes of umbilical pain are so numerous and varied that in order to mention all it would be necessary to enumerate nearly all abdominal complaints. This cannot be done here, but one should bear in mind the following as possible causes in patients in whom no trace of abdominal disease can be found, and who still complain of pain at or about the umbilicus.

Tabes Dorsalis.—The only complaint of the patient may be of abdominal pain, often referred to the region of the umbilicus. The typical gastric crises may be replaced by a much more diffuse pain, and more than one person has been operated on, and a gastro-enterostomy performed, under a mistaken diagnosis. A systematic examination of the knee-jerks, pupil-reflexes, etc., should be made in all cases.

Lead Poisoning.—Severe attacks of cramp-like abdominal pains referred to the umbilicus may be the chief, or even the only, symptom. The patient's occupation may suggest the diagnosis, or other characteristic signs of plumbism may be found (p. 45).

Tumour of the Spinal Column or Cord, Spinal Caries, and Compression Myelitis. Though a less common source of error, these must be borne in mind. Owing to its situation, a growth in the spine may be very hard to locate : a skiagram may be of service.

Phthisis.—In this disease gastric pains are a common symptom, and the pains may even be referred to the umbilicus. *George E. Gask.*

PAINFUL COITUS. (See DYSPAREUNIA, p. 239.)

PAINFUL MICTURITION. (See MICTURITION, ABNORMALITIES OF, p. 190 : and PAIN IN THE PENIS, p. 574.)

PAINFUL SWALLOWING.—(See DYSPHAGIA, p. 210.)

PALLOR.—(See ANÆMIA, p. 26.)

PALPITATION signifies the sensation experienced by a person who is conscious of his heart-beats. It is not necessarily associated with pain. It may be due to many different causes, of which the following are the chief :

1. Valvular Heart Disease, especially :—

Mitral stenosis	Aortic stenosis	Pulmonary stenosis.
Mitral regurgitation	Aortic regurgitation	
Mitral stenosis and regurgitation	Aortic stenosis and regurgitation	

2. Heart Affections associated with High Blood-pressure :—

Arteriosclerosis	Granular kidney.
------------------	------------------

3. Myocardial Affections :—

Fatty heart	'Blacksmith' heart	Senile changes
Fibroid heart	Cloudy swelling	Congenital deformity
Primary alcoholic heart	Pericarditis	Coronary artery atheroma.
	Adherent pericardium	

4. Lung Affections leading to Failure of the Right Side of the Heart :

Chronic bronchitis	Fibroid lung
Emphysema	Large pleural or pleuritic effusion.

5. The Effect upon the Heart of certain Drugs, etc. :

Tobacco	Absinthe	Thyroid extract
Tea	Morphia	Cordite.
Coffee	Cocaine	
Alcohol	Digitalis	

6. Heredity, Nervousness, and Allied Causes :

Fright or other emotion	Paroxysmal tachycardia	Epilepsy
Graves' disease	Neurasthenia	Tabes dorsalis.
	Hysteria	

7. **Anæmia** from whatever cause, but particularly :

Chlorosis

Pernicious anæmia.

8. **Mechanical Interference with the Heart by :** —

Mediastinal new growth

Ascites

Chronic mediastinal fibrosis

Pregnancy

Large thoracic aneurysm

Ovarian cyst or other large intra-abdominal tumour.

Tympanites

9. **Dyspepsia** : especially that which is associated with flatulence and with stoutness from lack of exercise.

The majority of patients who complain of palpitation jump to the conclusion that they have something the matter with the heart, and, although the above list is a long one, the diagnosis resolves itself in all but a few cases into deciding whether the palpitations are cardiac in origin or not. A routine examination of the various systems will very often indicate the correct diagnosis at once.

Valvular heart disease will be indicated by the history of rheumatic fever, scarlet fever, chorea, syphilis, or the like, and by the alteration in the size of the heart, together with the various bruits. Mitral stenosis is sometimes more difficult than the others to diagnose on account of the possible absence of a bruit or of enlargement of the left ventricle, but it may be suggested by the patient's malar flush, by the history of acute rheumatism, and by the loud, sharp, snapping character of the first sound at the impulse. Aortic regurgitation is sometimes present without a bruit, but it can generally be detected in these cases by the typical collapsing character of the pulse : if there is still doubt, and the patient is able to take exercise, it is frequently possible to bring out an aortic regurgitant bruit by asking him to take a few steps briskly.

High blood-pressure conditions are best detected by means of a sphygmomanometer : the diagnosis will be confirmed by the big heart, the albuminuria with tube-casts, and in advanced cases perhaps by retinal hæmorrhages or retinitis.

Of the *myocardial affections*, pericarditis and cloudy swelling are both acute conditions, often associated with fever and with sufficient general illness to confine the patient to bed, so that the palpitations are a minor part of the malady. The diagnoses of fatty or fibroid heart and of adherent pericardium are discussed on pp. 69, 70, 71. Palpitations due to heart-muscle affection are sometimes most difficult to distinguish from similar palpitations due to dyspepsia. This applies particularly to fatty changes in the heart. Not a few middle-aged persons suffer from palpitations which, by some observers, will be attributed to gastric trouble, whilst by others both the palpitations and the dyspepsia will be attributed to fatty heart : nor can the diagnosis be made by watching the effect of slight exercises upon the pulse-beat, for in typical dyspeptic persons without fatty heart the general condition is usually sufficiently lacking in tone for the pulse-rate to be increased readily by exercise. If material benefit results from the giving of digitalis, from the adoption of Schott's Nauheim treatment, or some modification of the latter, the argument will be in favour of some myocardial degeneration : but in many instances of flatulence and palpitation the diagnosis between fatty heart and mere dyspepsia will remain largely a matter of opinion. Electrocardiograms may throw light upon the nature of some cases of myocardial disease the nature of which is not obvious to percussion and stethoscopic examination only : auricular fibrillation may be found, for example (*Fig. 461*), or a broken apex to the R spike showing that the ventricular muscle is affected, or reversal of the R spike in Lead 3 as compared with its direction in Lead 1 (*Fig. 109*, p. 122), indicating organic departure from the normal, though there may be no valvular disease.

Lung affections causing strain of the right ventricle, and thus leading to palpitations, are detected as a rule by physical examination, but here again there may be so much difficulty in interpreting the physical signs, that when a stout, middle-aged person, with obvious emphysema, and with wheezing and shortness of breath on exertion, complains of dyspeptic symptoms and also of palpitations, it may be very difficult indeed, except by watching the effect of different lines of treatment, to say whether the actual cause of the palpitations, is emphysema with secondary dilatation of the heart, or dyspepsia with reflex palpitations, or the result of fatty changes in the heart muscle of a dyspeptic person of sedentary occupation who is both stout and emphysematous.

Tobacco is a very important cause for palpitations in a patient who may seem to be perfectly healthy: the degree to which different individuals can smoke tobacco with impunity varies enormously, and whereas some may smoke from morning to night and develop no untoward symptoms at all, others develop some ill-effects from what are relatively quite small quantities. Cigarettes seem to be the greatest offenders in this respect. In bad cases the heart becomes absolutely irregular: in all cases of the kind any extra exertion, such as trotting a hundred yards, causes a rise in the pulse-rate out of all proportion to what it should: the pulse may rise, for instance, from 70 to 150 or 160 per minute as the result of slight exertion which in an ordinary individual would only increase it to 90 or 100. These patients may have palpitations at any time of the day or night, but particularly when they first get into bed, when violent thumpings may cause them considerable alarm. Similar thumpings of the heart, closely allied to but hardly identical with palpitations, are complained of by elderly men, particularly those of the gouty habit, probably with atheromatous degeneration of their coronary arteries. Another condition in which the heart may produce similar symptoms is *epilepsy*, in which disease, quite apart from the major attacks, there are innumerable accessory symptoms, of which cardiac thumpings in bed at night-time are one. In that particular variety of epileptiform convulsions which is associated with a sudden halving of the pulse-rate and coma

FIG. 461. Electrocardiogram illustrating auricular fibrillation. Ventricular beats are marked R. The auricular beats are unmarked except in the central part of the middle curve, where three of them are marked x x x. The ventricular beats (R) do not recur at equal intervals, so that the pulse was irregular in time; but the average ventricular rate was 100 per minute. The auricles were not beating regularly; but where marked x x x the beats occurred approximately one every fifth of a second, the auricular rate at this point being about 300 per minute (auricular flutter). Time markers in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

Stokes-Adams' syndrome palpitations may also be a prominent symptom: the diagnosis is

established best by obtaining electrocardiographic records, these being the most adequate means of excluding or confirming the existence of partial or complete heart-block (see Figs. 101, 104, pp. 108, 109). *Tea, coffee, alcohol, and absinthe*, as causes of cardiac irregularity and consequent palpitations, can be diagnosed best by the history and by the effects of stopping the drugs in question. *Morphia and cocaine*, if taken over periods sufficiently long to lead to palpitations, will generally be indicated by the presence of multiple prick-marks upon the body or limbs. The palpitations and other cardiac symptoms are worse, not while the drug is being taken, but when it is being intermitted. *Digitalis* and *thyroid extract* will be recognized as the cause at once if they are being prescribed by the medical attendant. *Cordite* may be chewed secretly by a malingerer who wishes to produce heart symptoms and signs for purposes of deception: for instance, by a recruit wishing to escape army service, or by a person desirous of augmenting a claim for compensation after an accident.

When palpitations are due to *nervousness, fright, or other emotion*, they are transient and not difficult to diagnose: if they keep on recurring from apparently trivial causes in a person who has not hitherto been nervous, it is important to bear in mind the possibility of *Graves' disease*, for although exophthalmos and enlargement of the thyroid gland are important symptoms of this disease it is not uncommon for them to be absent in the early stages, the only signs of the malady then being undue nervousness with a tendency

to tachycardia and palpitations. Any condition in which the nervous system seems to be lacking in force or in control is liable to be termed *neurasthenia* nowadays, and if neurasthenia be defined in this broad sense, then one variety of it has palpitations for a chief symptom: the making of a diagnosis of neurasthenia in such cases, however, is equivalent to saying that the palpitations are of purely nervous origin, so that all one has really done is to exclude organic changes. The same applies to *hysteria*, though it should be borne in mind that modern authorities distinguish between *hysteria* and *neurosis*, confining the word hysteria to those cases in which the symptoms are directly controllable by suggestion. A label for functional disorders of the heart that were common in the great war is still in general use—D.A.H., or disordered action of the heart: the patient suffers from definite and real symptoms, particularly from palpitations on exertion or under excitement, a ready tendency to tachycardia, precordial discomfort amounting even to pain, shortness of breath on trivial exercise, and a tendency to turn faint without adequate cause. The condition may prevent the individual from doing a full day's work, and interferes materially with occupation and duty: but it is important not to confuse such cases with real cardiopathies, for they are in no cardiac danger, have normal heart muscle and heart valves, and should be encouraged to exert themselves up to the limits of their cardiac powers, instead of the reverse. The condition is the same as that which was formerly called *soldier's heart*: the disorder is not in the heart itself, but in the nerves controlling the heart—a central vasomotor disturbance, as it were, and not a disease. The damage to the sympathetic nervous system may have been brought about by fright, shock, accident, injury: or it may be almost an inborn state of instability without external cause: and in either case it is accentuated by the action of almost any form of microbic toxins—previous influenza, for instance, or septic teeth or tonsils, intestinal infection, nasal sinus disease, various tropical infections, and so on: it was a common and very troublesome after-effect of *trench fever*, persisting sometimes for years after the main illness had passed by. In making the diagnosis of D.A.H. it is important to exclude organic heart disease by all the ordinary methods at our disposal, including X-ray measurements of the heart shadow and the taking of electrocardiograms. The treatment, when the diagnosis of D.A.H. is established, is treatment for the nervous system rather than for the heart itself.

Locomotor ataxia may give rise to symptoms referable to almost any of the viscera, and there seems no reason why cardiac crises should not occur as much as laryngeal, gastric, or intestinal: they are, however, rare, and when cardiac symptoms develop in a patient suffering from locomotor ataxia, syphilitic affection of the heart would be a more likely diagnosis than would cardiac crises.

Anæmia, when it produces palpitations, is usually obvious from the patient's appearance, and it can be confirmed by blood examination. As a rule, palpitations in anæmic patients are absent while the patient is at rest in bed, occurring mainly when she exerts herself and causes temporary dilatation of the anæmic heart. The palpitations disappear when the anæmia is cured.

Palpitations due to *mechanical interference with the heart* by masses or fluid or wind displacing it, can generally be relegated to their correct cause by physical examination of the chest and abdomen: mediastinal new growth, tympanites, ovarian cyst of large size, and the other conditions referred to above, generally make their presence obvious before they are of sufficient size to produce palpitations.

Herbert French.

PAPULES may be defined as solid, circumscribed elevations of the skin, not larger than a pea. Similar formations exceeding that size are classed as nodules or as tumours. From VESICLES (p. 913) they are distinguished by their solidity: if a papule is punctured, nothing but blood exudes: but in many instances papules, especially those of an inflammatory kind, are transitional lesions, passing into (a) vesicles, (b) pustules, (c) scales, or (d) breaking down into ulcers, (e) undergoing hypertrophy, as warts, or (f) atrophying. If the transformation into pustules or vesicles is only partial, the lesions are described as papulo-pustules or papulo-vesicles, and if this is characteristic of the greater number of the lesions, the eruption is said to be papulo-vesicular, vesiculo-papular, or papulo-pustular. If the lesions, originating as erythematous macules, do not take on the full character of papules, they are said to be maculo-papular or erythemato-papular.

In size, papules may vary from a pin's head, as in *lichen scrofulosorum*, to a pea, as

in lichen ruber planus. The most typical *shape* is that of the papule of lichen planus, flattened and with an irregular base ; but they may be rounded or oval, as in prurigo, or cone-shaped, as in pityriasis rubra pilaris, or triangular, or umbilicated, as in lichen planus. In *colour*, they may be pink or rose-coloured, as in the inflammatory papules of urticaria papulosa, violet or purplish as in lichen planus, bright red as in eczema, dark or coppery as in syphilis, yellow as in xanthoma, whitish as in milium, almost black as in melanotic carcinoma, or simply skin-coloured, as in prurigo or verruca plana. They may be discrete, as in prurigo, or may occur in patches, as in lichen scrofulosorum ; sometimes they form round a hair follicle, as in eczema folliculorum and pityriasis rubra pilaris ; they are also met with in connection with the sebaceous glands, the sweat-glands, or the papillae. They may be inflammatory, as in eczema, or non-inflammatory, as in severe goose-skin, or when they are the result of retained secretion, as in acne, or of excessive cornification round the mouths of hair-follicles. Usually, inflammatory papules give rise to itching ; with the non-inflammatory kind there are seldom marked subjective symptoms.

Papules may occur in the epidermis, as in verruca plana, or in the derma, when they may be oedematous, as in urticaria, or infiltrated, as in lichen scrofulosorum ; or they may affect both structures, as in lichen planus and acute prurigo. The epidermic papule may be recognized by its solidity, hardness, dryness, and superficial elevation ; the oedematous dermic papule by its pinkish colour and its momentary yielding to pressure ; the infiltrated dermic papule by its redness, induration, and elasticity ; the epidermo-dermic papule by its union of some of the characters of the other varieties.

The multiple small papules which occur in *papular eczema* are usually conical with rounded base and bright-red colour ; owing to rupture by scratching they are covered with a tiny dome of blood-crust ; there is usually intense itching. Eczema of this type may resemble *lichen ruber planus*, but in that affection the papules, as a rule, are flat or umbilicated, with an irregular base, dark-red or violaceous colour, and glistening surface ; there is no discharge or crust-formation ; the papules are not transitional, and they leave brownish stains, while those of eczema frequently pass into vesicles and seldom produce discoloration. Confusion between the plaques of lichen planus and those of scaly eczema may be obviated by attention to the differences in colour and in definition ; in the former the plaques are generally dark-red or purplish, and sharply defined ; in the latter, bright-red and not clearly marked off from the surrounding skin. Under the lens, a minute vesicle can often be seen on the top of each papule in eczema, while those of lichen planus are flat and burnished. Yet another point of distinction between the two is that in lichen planus characteristic discrete papules can usually be found at the margin of the patches. This feature serves, too, to differentiate lichen planus, in its turn, from *generalized psoriasis*, which is marked also by more scaliness and less thickening.

Lichen scrofulosorum is a papular dermatosis which clinically bears some resemblance to lichen planus, but it has no right to the designation lichen, and belongs to the tuberculides.

Papules are seldom larger than a pin's head, are usually flattish but occasionally conical, slightly resistant to the touch, sometimes smooth and shiny but more often covered with a tiny scale which is but slightly adherent ; occasionally the summit is occupied by a pustule instead of by a scale. The prevailing colour is red, but it varies from a pale-yellow through red to violet. At first the lesions are disposed in groups, forming patches of various sizes. Others are arranged in arcs of circles, which are usually seen about the orifices of the sebaceous glands. The eruption shows a distinct predilection for the trunk—the lower part of the abdomen and the back ; but occasionally it extends to the beginnings of the limbs and may invade the face. If the affection becomes generalized by the spread and coalescence of the scattered groups of papules the whole skin is covered with thin scales and is of a dirty reddish-brown hue. Itching is absent, or so slight as to be negligible. The eruption begins insidiously and may last for several months ; and, having disappeared, leaving behind it no trace, it may reappear again and again over a period of several years. In the great majority of cases the disease is associated with some form of tuberculosis—phthisis, or necrosis of bone, or scrofulous ulceration of the skin ; but more commonly with enlarged glands, submaxillary, cervical, or axillary. Its usual subjects are children and adolescents ; it is uncommon after the age of twenty. The characters of the papules—their homogeneity, situation on the trunk, flattish shape, arrangement in groups, painlessness, and chronicity—with the absence of itching, and the youth of the patient, are generally

sufficient to determine the nature of the affection. In papular eczema the papules are not limited to the trunk, are bright red, and there is troublesome itching: moreover, in many cases there are vesicular or papulo-vesicular lesions as well as papules. From *miliary papular syphilides* *lichen scrofulosorum* can be distinguished by the absence of any other sign of syphilitic affection, and by the usually restricted distribution of the lesions.

In *keratosis pilaris*, or *xerodermia*, the papules do not form groups or patches as in *lichen scrofulosorum*, and usually they appear on the extensor surfaces of the limbs, most frequently the thighs: they consist of projecting hair-follicles, which convey to the hand the sensation of a nutmeg-grater. This affection has, in turn, to be distinguished from *goose-flesh*, in which the elevations, besides being evanescent, are not rough or scaly. Keratosis pilaris is one form of *ichthyosis*: another form, sometimes met with in association with xerodermia, but more often alone, is *ichthyosis hystrix*, in which the lesions consist of

Fig. 162. Ichthyosis hystrix. A. Anterior aspect of the patient, showing multitudes of small papules in streaky groups over the chest and abdomen, with more definite warty excrescences in the left armpit and the side of the neck. There is decided pigmentation of the skin in the ichthyotic patches. B. The posterior aspect of the neck and trunk. (Photographs kindly sent by Dr. John Simons, Penzance.)

small warty papules with horny tops, which stud the skin as with minute nail-heads, and sometimes develop into large warty masses (*Fig. 162*). The condition, dating back to infancy, or at least to early childhood, is easy of identification.

The same may be said of the ordinary wart (*verruca vulgaris*). The small flat wart (*verruca plana juvenilis*) may sometimes suggest *lichen planus*, but it is smaller than the papule of that affection, it has not the dark colour, it gives rise to no itching, nor is there any tendency for the growths to run together into rough, scaly, infiltrated patches.

In *pityriasis rubra pilaris*, papules form at the orifices of the hair-follicles, usually following in the wake of an eruption of scaly patches, or of a dry eruption covered with eczematous-looking crusts. The papules, when they appear, are small, red, and dry, harsh to the touch, more or less conical, and the centre of each is pierced by a single atrophied hair, which is surrounded by a sheath that penetrates into the follicle. The surface of the

integument, thus roughened, has been likened to the skin of a newly-plucked fowl. At first the papules are discrete, but later they tend to run together into patches which present the aspect of pale yellowish-red areas covered with papery scales resembling mica. They mostly affect the limbs, especially the surfaces where hair is most abundant; if they eneroach upon the trunk they are usually found at the waist and the lower part of the abdomen. Itching is sometimes absent, and when present is always insignificant. When the patches are covered with mica-like scales and are met with in the situations most common to psoriasis—the tips of the elbows, fronts of the knees, and the extensor surfaces of the limbs—there is some danger of confusion with that disease; but at the edge of each patch the characteristic conical papule with its single hair plugging the mouth of a follicle is always to be seen. The best place to look for the papule is on the dorsal surfaces of the first phalanges of the fingers. In psoriasis, again, the lesions grow by peripheral extension instead of by the accretion of new papules. The fact that the general health is not affected suffices to mark off pityriasis rubra pilaris from other forms of *exfoliative dermatitis*, in which also there is rarely any appreciable thickening of the skin, while the colour is redder than in pityriasis and the scalliness more marked. From *lichen ruber planus*, pityriasis rubra pilaris is distinguished by its greater chronicity and the larger areas usually involved, by its affecting the scalp, by the absence of itching and of the violaceous, flattened and often umbilicated papules characterizing the former disease.

In *aene vulgaris*, the papule forms the primary lesion. If the obstruction is at the mouth of the sebaceous gland-duct the plug appears on the surface as a small black point—the comedo: if it is in the gland itself, the obstructing material is seen as a tiny whitish mass in the substance of the skin—the milium. The lesion may not develop beyond this stage, but usually it grows into a reddish papule about the size of a pea, and the papule generally passes into a pustule. Aene can usually be recognized by the distribution of the lesions—on the face, especially the cheeks, nose, forehead, and chin, and less frequently the back of the neck, the back between the shoulders, and the chest—their discrete character, the presence of comedones or of milia, and the patient's age, for the affection is essentially one of puberty and adolescence. Usually, too, the several stages through which the lesions pass are present at the same time—the comedo or milium, the papule, the pustule. *Rosacea* differs from aene in that it chiefly affects the flush area of the face, is marked by much congestion, and is most common in middle life. (See also PUSTULES, p. 681.)

In *erythema multiforme*, papules, tubercles, vesicles, bullæ, nodules, macules may all be present at the same time. Any one of these lesions may be predominant in a particular case or at a given time; but the type of eruption most frequently met with is that which consists wholly or predominantly of papules—*erythema papulatum*. This, too, is usually the first stage of the eruption in cases which go on to other types. The papules are generally, at the beginning, no larger than a pin's head, bright-red in colour, and flattish, sometimes umbilicated. If grouped closely together they may coalesce and form raised patches as large as a threepenny or a sixpenny piece; each patch has a sharply defined oedematous centre; the tint in the centre soon deepens to violet, and afterwards to purple. The favorite sites are the dorsal surfaces of the hands and forearms; but the legs, feet, and the face may also be involved. Papular erythema multiforme is, as a rule, easy of recognition. Urticaria of the papular variety—the *strophulus* or *prurigo simplex aiguë* of French dermatologists—in which the wheals are no larger than a lentil, and leave papules when they subside, occasionally offers some resemblance to it; but the two affections differ in that the lesions of erythema papulatum are much more persistent, are not white in the centre, do not give rise to itching, and do leave stains. One of the most marked of these differences is that which concerns itching, for in papular urticaria this symptom, though variable, is frequently severe. In urticaria, too, it is chiefly the covered portions of the body that are attacked, and the affection is met with mostly in children.

Papules like those of urticaria papulosa are often met with in *prurigo*, both in *prurigo ferox* of Hebra, the severe form of the affection, and in *prurigo mitis*, the mild and ordinary form. The characteristic lesion is an eruption of discrete, firm, very slightly raised papules, more or less hemispherical in shape, with a roundish, sometimes oval contour, and a glistening surface. At first the papule is of the same colour as the skin, but afterwards it becomes red, yellowish, or brownish, increases in size, and is frequently covered by a blood-crust. In structure it is a localized acanthosis. Most abundant on the extensor surfaces of the

limbs, and rarely seen on the flexor aspects, or on the face, the papules occur not infrequently on the chest, the lower part of the abdomen, the sacral region, and the buttocks. The itching is intense, and, mixed with the secondary changes produced by scratching, there may be found others of an eczematous character. Pustules and sores are common, often accompanied by great enlargement of the axillary and femoral glands. In *prurigo ferox* the papules are much larger and more numerous, and in parts the skin feels to the touch like very coarse brown paper or a nutmeg-grater. The changes secondary to the inflammatory process in *prurigo* are summed up by French dermatologists in the term *lichenisation* or *lichenification*. The skin is thickened and rugose, and owes its peculiar aspect to an exaggeration of the fine striae of the normal integument, so that it becomes quadrillated into a network of which the meshes are square, lozenge-shaped, or polygonal, with a flat surface which often presents the aspect of glossy and brilliant facets, as of a mosaic. Sometimes it is covered with fine scales. The skin is less supple than normal skin, and though in colour it may undergo no change, it is more often greyish or brownish. The condition has to be distinguished from the lichenization met with in other dermatoses. In eczema and psoriasis the thickened and rugose skin is red, has no glistening facets, and the margins are clearly defined. In lichen planus the plaques are formed by confluent papules and are surrounded by characteristic papules.

Apart from these secondary characters of *prurigo*, the diagnosis is made by excluding other itching affections, such as *scabies* and *pediculosis*, on account of the absence of the lesions characteristic of those conditions, and by the positive characters—the origin of the affection in infancy, and its persistence, the poor general health, the preference the papular eruption shows for the extensor surfaces of the limbs, the freedom of the bends of the joints, and the glandular enlargement, especially in the inguinal region.

In Syphilis, papules are met with frequently in association with macules, but they may occur independently. They may be divided into two main classes: (1) *Miliary papular*, and (2) *Flat papular syphiloderms*.

1. *Miliary*, or *follicular*, *papular syphilides* are the result of infiltration around and beneath the pilo-sebaceous follicles: they are rough to the touch, and feel like small shot; they vary in size, from a pin-head upward, and may be either acuminate or rounded. The sites of election are the trunk, back, shoulders, and loins, but the limbs may be invaded, and also the face. Very frequently the lesions appear in groups which run into each other; and they are sometimes disposed in rings. The characteristic colour is that of raw ham, but at first they may be pink or red. Involution proceeds slowly, the stain left behind is long in dying away, and is sometimes succeeded by a shallow depression which may last for years. There is often a slight scale on the surface of the papule, and not seldom a tiny vesico-pustule or pustule may be detected on the summit. Sometimes there is overgrowth of the papillae; and if the lesion is situated in a moist part the warty growth is covered with sodden white epithelium, when the lesion is known as a *mucous papule*. A more marked degree of hypertrophy transforms the moist papule into a *mucous tubercle* or *condyloma*, distinguishable from a wart in that the overgrown papillae are welded into a coherent mass by swelling of the intervening tissue, while in the wart they are free.

2. *Flat*, or *lenticular*, *papular syphilides* vary in size from a pin-head to a bean, and the small or the large lesions may predominate in a given case. They may develop directly out of macular syphilides. In contour they are almost perfectly round, with a flattened top, are but slightly elevated, and in colour usually brownish-red. Any part of the body may be affected; there is little tendency to agmination; sometimes the lesions form a kind of circle on the brow round the margin of the hair (the *corona veneris*). In some cases ring-like patches (the circinate or annular syphiloderm) appear on the chin, around the lips or nostrils, or sometimes on the vulva; they are made up of small yellowish-red papules, with fine scales; elsewhere the papules, in the same case, are of the ordinary kind. In other instances, the flat lenticular papules of this group become seborrhœic; these are characterized by their obduracy to treatment. When there is marked scale-formation, the papules being covered with a dry, dirty-grey scale, they are styled papulo-squamous. Favourite situations for papulo-squamous syphiloderms are the palms and the soles, where they may be mixed with maculo-papular and papulo-tubercular lesions. Syphilides in these sites are often rounded or irregular in shape, have but slight elevation, are at first brownish-yellow or brownish-red, but presently become of a dirty grey, and on

the disappearance of the scales have the characteristic colour of raw ham. When the scales are more horny than usual, they form the *syphilides cornées* of French dermatologists.

The small papular syphilides may in some cases be difficult to distinguish from a widely diffused lichen ruber planus: but in this affection the rash is uniform, the papules generally have a linear arrangement, and there is usually severe itching. The papules of syphilis are most likely to be confused with psoriasis the squamous papules with the ordinary form of psoriasis, the papules in rings with annular psoriasis. Attention must be paid to the polymorphism of the syphilitic eruption, the coppery colour, the enlarged glands, the sore throat or tongue, and the distribution of the lesions, no such partiality for the elbows and knees being shown as is observed in psoriasis, and the papular syphilide having a preference for the flexor surfaces of the limbs, while psoriasis affects rather the extensor aspects. The syphilitic scales, too, are thin and dirty-white, while those of psoriasis are heaped up in layers and have a silvery sheen. In psoriasis, the subject will usually have a history of previous attacks to relate; and often the affection can be traced back to early life, whereas in syphilis a particular lesion is seldom repeated. The palmar and plantar syphiloderms described above, which occur symmetrically as secondary and unilaterally as tertiary lesions, may be confused with the dry chronic eczema of those regions; but in eczema there are heat and itching, and usually, in the case of the palms, the fingers also are involved, and at some point or other the process is vesicular or moist. Palmar syphilides may be distinguished from eczema seborrhœicum by the fact that in the latter there are coincident lesions in the common situations the scalp and eyebrows, the neighbourhood of the beard, the naso-labial folds, the sternal and interseapular regions; nor do they usually assume the form of crescents or segments. Whenever the diagnosis is doubtful, recourse may be had to Wassermann's serum test.

Ernest Dore

PARÆSTHESIA. (See SENSATION, ABNORMALITIES OF, p. 747.)

PARAGEUSTIA.—(See TASTE, ABNORMALITIES OF, p. 859.)

PARALYSIS OF BOTH LEGS. (See PARAPLEGIA, p. 621.)

PARALYSIS, CROSSED.—(See HEMIPLEGIA, p. 381.)

PARALYSIS, FACIAL. This term is applied to complete or partial paralysis of the muscles supplied by the 7th cranial nerve. One or both sides of the face may be involved, the unilateral being more common than the bilateral. It is in some cases the result of a morbid process limited to the 7th nerve, known as *Bell's palsy*; in other instances it is one of the signs of more complex, or more remote, disease. In complete unilateral facial palsy, whatever its origin, the asymmetry of the face may be so marked that the diagnosis can be made at sight. Less severe facial weakness may be overlooked unless the means for its detection are employed. It is well, therefore, to recall the evidences of facial palsy before pointing out the features which characterize its various forms.

Even with the face at rest there are certain appearances on the affected side which attract attention. The natural lines and wrinkles are less marked, and, with the obliteration of the naso-labial fold, the cheek has a somewhat flattened or, in old persons, baggy aspect. If the patient is unconscious or asleep, the flabbiness of the tissues may be emphasized by the flapping of the cheek with respiration, especially if breathing is laboured or stertorous. The palpebral fissure is wider than its fellow, and the corner of the mouth may droop.

Fig. 463. Paralysis of the right side of the face, the patient attempting to show her teeth. Note that the right palpebral fissure is wider than the left. (*Bull. Br. S. A. L., Wilson.*)

When the facial muscles are thrown into action by attempts to raise the eyebrows, to close the eyelids, or to expose the teeth (*Fig. 463*), the difference between the two sides is rendered more obvious, the movements on the parietic half of the face being carried out with less power and more slowly than those of the healthy half. The ability to whistle or to move one nostril may also be impaired,

and even with slight degrees of paresis a person who has previously been able to close the eye of the affected side, the other eye remaining open, is no longer able to perform the feat. The same difficulty is experienced in making movements of the ear by patients who have formerly possessed that accomplishment.

Having established the presence of some facial weakness, it is necessary, in order to take full advantage of its diagnostic value, to make certain careful observations with a view to determining the site of the lesion which is responsible for the defect. Thus, facial paralysis may be brought about by : (1) A lesion anywhere in the course of the pyramidal fibres passing from the lower end of the precentral gyrus in one cerebral hemisphere to the facial nucleus on the opposite side of the pons Varolii (*supranuclear paralysis*) ; (2) A lesion involving the facial nucleus itself (*nuclear paralysis*) ; and (3) A lesion of the 7th nerve between its origin in the nucleus and the point where it divides in order to supply the various facial muscles (*peripheral paralysis*).

Supranuclear Paralysis. Owing to the fact that the fibres of the pyramidal tract concerned with facial movements cross the mid-line of the brain-stem only a very short distance above the 7th nucleus, the facial paralysis is on the side opposite to the lesion. Occasionally these fibres are involved alone ; more often those destined to the corresponding arm and leg suffer as well, in which case the facial palsy forms part of a hemiplegia. In this type of paralysis the difference between the two sides is not nearly so marked in the upper as in the lower half of the face. For instance, the patient is able to elevate both eyebrows and to close both eyes, although it will be found, on testing, that he is not able to resist an attempt on the part of the observer to open the eye of the affected side with the same degree of success as attends his efforts on the healthy side. In the attempt to expose the teeth the facial asymmetry is more striking, the lip remaining immobile or retracting slowly and feebly on the parietic side, and the contrast between the depth of the naso-labial folds on the two sides becoming clearly emphasized.

Notwithstanding the impairment of voluntary movement on one side, the face may present perfect symmetry when it responds automatically to emotional or reflex impulses : in laughing or crying the lines and wrinkles are developed equally, while protective closure of the eyelids is accomplished as well on one side as the other in response to any threatened violence to the eyes. The preservation of these automatic movements depends on the integrity of a facial reflex centre in the mid-brain. When this centre is involved at the same time as the fibres of the pyramidal system, the emotional movements are lost or impaired along with those of voluntary origin.

The corneal reflex can generally be elicited in this form of facial paralysis, provided there is no co-existent diminution of sensibility within the area supplied by the trigeminal nerve of the same side. In sharp contradistinction to what obtains in the nuclear or peripheral types of palsy, the nutrition and electrical excitability of the facial muscles undergo no alteration when the lesion is situated above the nucleus.

Bilateral supranuclear paralysis, such as is seen in cases of cerebral diplegia and pseudo-bulbar paralysis, is characterized by a general impairment of the natural movements, and tends to the production of a stiff, expressionless physiognomy (*Fig. 164*). With the consequent defective inhibition of the reflex centre, emotional movements are often uncontrolled, and with little provocation the patient betrays in his face degrees of mirth or distress which he is very far from feeling. This condition can be distinguished from true bulbar palsy by the preservation of the nutrition and the normal electrical excitability of the muscles, and by the absence of accompanying atrophic paralysis of the tongue, masseters, etc.

Reference must be made to the occurrence of cases, the result of mid-brain lesions or of tumours of the temporal lobe, in which the emotional movements are lost and the voluntary movements are preserved on one side of the face. Asymmetry is then only noticeable when the patient smiles or cries.

Fig. 164. Bilateral facial palsy. The photograph shows absence of all lines, and sagging of both corners of the mouth.

In long-standing cases of infantile hemiplegia facial weakness may be associated with spontaneous athetoid movements similar to those observed in the arm and leg.

Nuclear Paralysis. Lesions of the facial nucleus may be slight or severe, and the resulting facial paralysis may consequently be partial or complete. As a rule, all the muscles supplied by the nerve are affected more or less equally, and the impairment of movements obtains whether they are voluntary, emotional, or reflex in origin. In cases of complete nuclear palsy certain additional effects are produced. The inability to close the eye, and the drooping of the lower lid, lead to imperfect protection of the eyeball, and to the overflow of tears on to the cheek (epiphora). Conjunctivitis and blepharitis may result. Paralysis of the lip muscles allows of saliva escaping from the corner of the mouth, and may interfere materially with the articulation of labial consonants. Paralysis of the stapedius muscle disorganizes the control of tympanic tension, so that the patient suffers from excessive sensitiveness to deep tones (hyperacusis) and perhaps from tinnitus. Unlike supranuclear paralysis, the nuclear form is accompanied by atrophy and alteration in the electric excitability of the facial muscles. In slow degenerative (usually bilateral) processes affecting the facial nucleus, the electrical response shows a quantitative modification: in acute destructive (usually unilateral) lesions of the nucleus, the paralysis is followed rapidly by the reaction of degeneration.

Owing to the situation of the facial nucleus in the pons, unilateral nuclear palsy may be associated with paralysis of the external rectus muscle of the same side and paralysis of the opposite arm and leg ('crossed' paralysis).

Peripheral Paralysis.—The clinical picture of a peripheral facial paralysis resembles in its most important details that which has already been described under the heading of nuclear paralysis. All the muscles supplied by the nerve are affected in more or less equal

Fig. 465.—Post-paralytic contraction of the left side of the face. At first glance the appearance suggests that the right side is the seat of paralysis.

Fig. 466.—Post-paralytic contraction, the same patient closing her eyes and showing the over-action of all the facial muscles on the affected left side.

Fig. 467.—Post-paralytic contraction. The same patient smiling, with an involuntary wink.

(By Dr. S. A. K. Wilson.)

degree, and the palsy is associated, within a short time of its onset, with atrophy and alterations in electrical excitability of the muscles concerned. The diagnosis between the two types depends chiefly upon the presence of additional symptoms resulting from interference with the function of neighbouring tissues, and this varies again with the exact site of the lesion in the peripheral course of the nerve.

A lesion affecting the fibres within the pons is likely to produce, in addition to the facial paralysis, external rectus palsy, together with other symptoms in proportion to the extent of the destructive process.

A lesion between the surface of the pons and the internal auditory meatus will probably interfere with the vestibular and cochlear parts of the 8th nerve, and so give rise to vertigo and impairment of hearing.

At the level of the geniculate ganglion, the chorda tympani is unlikely to escape, and the taste fibres coming from the anterior two-thirds of the tongue lose their function. At the same time, irritation of the ganglion may provoke an herpetic eruption on the auricle and around the external auditory meatus.

In the upper part of the Fallopian canal a lesion produces complete facial paralysis and loss of taste on the anterior part of the tongue; in the lower part of the canal the resulting symptoms are the same, with the exception that paralysis of the stapedius, with its consequent hyperacusis, does not occur. The nerve to the stapedius leaves the facial nerve between these two points. Involvement of the chorda tympani may also cause deficiency in the salivary secretion of the submaxillary and sublingual glands of the same side.

At the stylomastoid foramen, the effects of a lesion are limited to the facial nerve, the taste fibres being no longer in close apposition to the latter.

From the above data the site of any lesion causing peripheral facial palsy can be determined approximately, and it is only necessary to add that the term *Bell's palsy* is generally limited to cases in which the exciting cause, probably an acute inflammatory process, operates at some point within or just below the Fallopian canal.

From the diagnostic standpoint it is important to remember that a condition which often results from a long-standing Bell's palsy may produce a facial asymmetry capable of erroneous interpretation, unless the observer is familiar with it. This is the so-called *post-paralytic contracture*, which emphasizes the folds and lines on the affected side in such a way that the opposite side of the face may appear at first sight to be the weaker (*Figs. 465, 466, 467*). It will be noticed, however, that an attempt to close the eye is imperfectly carried out, and that the angle of the mouth is strongly, although involuntarily, retracted at the same time. Similarly, on asking the patient to show his teeth, he can only do so slowly and with effort, while the eye is almost closed on the same side by a powerful associated contraction of the orbicularis palpebræ. The only complaint of a girl suffering from a slight degree of this contracture was to the effect that she was unable to smile without at the same time giving the impression that she was winking.

Hysterical facial spasm is another condition which may suggest weakness of the opposite side of the face, but the nature of the defect will be made obvious when the whole face is put into action.

Facial hemiatrophy often simulates facial paralysis (*Fig. 468*): it may be differentiated by the fact that not only the muscles, but the bones and all the tissues of the face on the affected side are of smaller size than are those of the other side. E. Farquhar Buzzard.

Fig. 468.—Hemiatrophy of the left side of the face in an early stage. This condition is sometimes mistaken for facial palsy.

PARALYSIS OF THE HAND. (See ATROPHY, MUSCULAR, p. 78; CLAW-HAND, p. 141; HEMIPLEGIA, p. 381; and PARALYSIS OF ONE EXTREMITY, UPPER, p. 611.)

PARALYSIS, LARYNGEAL. Laryngeal paralysis is to be distinguished from interference with the vocal cords by inflammatory or ulcerative lesions, fixation of the arytenoid joints, and other affections which mechanically prevent free movements of the cords. The distinction can scarcely be made without careful examination of the parts with the laryngoscope.

In some cases, especially when bilateral abductor paralysis comes on suddenly, the symptoms may be urgent and extreme; in others, there may be no definite symptoms at all, particularly if there is but partial paralysis of one vocal cord, the other being freely movable and able to cross the middle line so as to meet its fellow for purposes of speech or coughing. In most cases the symptoms which point to paresis or paralysis of a vocal cord are a change in the character of the patient's voice, as noticed by himself or his friends, or difficulty in coughing effectually when need arises, or a change in the character of the voice produced by the act of coughing, even to the extent of its becoming the 'brassy cough' of an aortic aneurysm with paresis of one vocal cord, or the 'bovine cough' of bilateral adductor paralysis.

For purposes of differential diagnosis laryngeal paralysis may be divided into three main groups, namely: (1) *Functional*; (2) *Unilateral organic*; (3) *Bilateral organic*.

1. Functional Paralysis of the Vocal Cords has for its main symptoms aphonia without pain or discomfort, the patient being female oftener than male: she seems quite unable to speak otherwise than in a whisper, and there may be no other symptoms at all, or there may be associated functional disorder such as difficulty in swallowing owing to globus hystericus. This form of loss of speech is due to functional adductor paralysis during vocalization: but when the patient is asked to cough she does so with ease, and thus demonstrates that the adductor paralysis is not real, for one cannot cough properly without adducting the vocal cords. If the larynx is examined with the laryngoscope, the cords will be seen to move perfectly both with respiration and when the patient retches, though they may remain in the abductor position if the patient is asked to make any particular voice sound. The condition always gets well: it may pass off almost instantaneously as the result of local electrical application or of treatment by suggestion.

2. Unilateral Organic Affection of a Vocal Cord is obvious on laryngoscopic examination. It is nearly always the result of interference with the corresponding recurrent laryngeal nerve, and owing to anatomical differences between the two, the left is affected more commonly than the right. It may be paralysed by pressure from, or infiltration by, an *aortic aneurysm*: a *mediastinal new growth*: *secondary deposits* in the deep cervical or mediastinal lymphatic glands—for instance, in a case of squamous-celled carcinoma of the œsophagus: *lymphadenoma*: *gumma*: or *mediastinal fibrosis*, particularly, though not very commonly, in association with *syphilis*, or with *fibroid phthisis* affecting the upper part of the left lung. Rarer causes are *mitral stenosis*, in which the over-distended left auricle sometimes compresses and paralyses the left recurrent laryngeal nerve: *lobar pneumonia* of the left upper lobe—extreme stridor has been known to result during convalescence from the latter in consequence of the cord paralysis: *hydatid cyst* of the mediastinum or lung: *actinomyces* of the lung. The differential diagnosis between these various conditions will be found discussed elsewhere: X-ray examination of the thorax may be helpful. Paralysis of the left vocal cord in a man of about forty-five is always suggestive of an aneurysm of the distal portion of the arch of the aorta, particularly if the patient has had syphilis.

3. Bilateral Affections of the Vocal Cords are seldom due to thoracic aneurysm, but some of the other diseases mentioned in the preceding paragraph may extend far enough up into the root of the neck on the right side to reach and involve the right recurrent laryngeal nerve as it passes beneath the right subclavian artery, as well as the left recurrent laryngeal nerve as it turns round the arch of the aorta to the left of the left subclavian artery. Careful examination of the chest for evidence of *new growth* or of *syphilitic or tuberculous fibrosis* is necessary, therefore, before one is in a position to diagnose as an alternative cause *degeneration of the nerve-cells in the vagus centres in the medulla oblongata*. It should also be remembered that malignant enlargement of the thyroid gland, *secondary metastases of carcinoma in the deep cervical lymphatic glands*, extensive infiltration of the latter by *tuberculous processes*, or *lymphadenomatous* or *lymphosarcomatous* changes in them, may involve both recurrent laryngeal nerves as they lie on either side in the sulcus between the trachea and œsophagus, and thus cause bilateral paralysis of the vocal cords. When the paralysis is due to degeneration in the vagal nuclei there is generally abductor before combined abductor and adductor paralysis: when the affection is symmetrical from the beginning the bilateral adductor spasm may result in acute dyspnoea simulating diphtheria or acute suffocative œdema of the larynx and requiring immediate tracheotomy. More often, fortunately, one vocal cord passes through the stage of abductor paralysis into that of complete paralysis before the other is affected, so that the dangerous condition of simultaneous abductor paralysis of both vocal cords is avoided. The diagnosis depends upon the alteration in, or the loss of, voice, together with the inability to cough efficiently, except with the sound which simulates the coughing of a cow (bovine cough): upon observation of the bilateral paresis of the cords with the laryngoscope: upon the exclusion of gross lesions within the thorax, or in the neck: and upon the co-existence of other indications of changes in the central nervous system. These in younger people are generally the result of syphilis, often associated with strabismus, or locomotor ataxy, or general paralysis of the insane: in older people, of vascular degeneration with concomitant evidence of bulbar paralysis or more general cerebral softening, with or without albuminuria, glycosuria, thickened arteries, an enlarged heart, and a high

blood-pressure; in rare cases the symptom may be due to hemorrhage or neoplasm in the medulla oblongata.

Very occasionally bilateral vocal-cord paralysis has resulted from surgical damage to the recurrent laryngeal nerves in the process of removing a large and difficult thyroid gland, especially a malignant one; if the nerves have been damaged but not destroyed the vocal cords may be liable to adductor spasms with intense stridor. *Herbert French.*

PARALYSIS, OCULAR. (See DIPLOPIA, p. 220; PUPIL ABNORMALITIES OF, p. 674; and STRABISMUS, p. 797.)

PARALYSIS OF ONE EXTREMITY (LOWER).—The diagnosis of the conditions in which paralysis of both legs occurs is dealt with under PARAPLEGIA (p. 621); the present article refers only to cases in which paralysis of one leg is complained of. It is, however, a common experience for the clinician to find signs pointing to a bilateral affection when the patient is only aware of disability affecting one lower extremity. A notable and common example of this is afforded by many cases of disseminated sclerosis. The patient complains of weakness in one leg, and the physician finds exaggeration of both knee-jerks as well as extensor plantar responses on both sides, and is led to the conclusion that both pyramidal tracts are affected, although one may be damaged more severely than the other.

The various types of crural monoplegia may be divided roughly into two classes, one of which includes those cases without muscular atrophy, and the other those which present greater or less degrees of muscular wasting.

Paralysis of One Leg without Muscular Atrophy. The cases in this class may be subdivided into two groups, the first comprising those in which the pyramidal tract is affected, and the second those in which there is no evidence of pyramidal affection.

Spastic paralysis of one leg may result from a lesion of the pyramidal tract in any part of its course, but for anatomical reasons it is more likely that the paralysis will be confined to one side when a lesion affects the opposite cerebral hemisphere above the pons, that is to say, above the level at which the two pyramidal tracts run in close proximity. Spastic paralysis of one leg may, however, result from a lesion at any level, and the diagnosis of the level must be made from a consideration of other symptoms. In all cases the condition of the leg is qualitatively, if not quantitatively, the same. A spastic leg is characterized by a certain amount of weakness and rigidity, exaggeration of the knee- and ankle-jerks, and the extensor type of plantar response. It is useful to remember that the weakness in a spastic leg does not affect all the movements to the same extent. If the movements of the various joints are tested against the observer's resistance, it will generally be found that dorsiflexion of the ankle and flexion of the knee are affected more than other movements. It is for this reason that the patient tends to drag his toes more on the affected side than on the other, and evidence of this is often forthcoming in the fact that he wears away the toe of the corresponding boot. The muscles of a spastic leg show no localized wasting, and present no alteration from the normal in their response to electrical stimulation.

In the attempt to diagnose the level of the lesion which gives rise to spastic paralysis of one leg certain considerations are of particular importance. If the lesion is situated immediately above the lumbar enlargement of the cord, the abdominal reflexes can be obtained. If the lesion is situated at the level of the 10th dorsal segment, the lower abdominal reflex on that side will be absent, while the epigastric reflex remains intact. A lesion of any of the upper dorsal segments causes abolition of all abdominal reflexes on the corresponding side. A lesion above the cervical enlargement will lead probably to some, even if slight, weakness in the corresponding upper extremity, in which the tendon-jerks will be exaggerated. A lesion of the higher part of the pons or of any level between the pons and the cerebral cortex will produce some asymmetry in the facial movements as well as weakness in the arm and leg.

Disseminated sclerosis has been mentioned already as a disease in which spastic paralysis of one leg may result from a lesion situated in the spinal cord. In all probability evidence of other patches of disease will be discovered in such cases if a careful examination is made. Some intention tremor in one or both hands, nystagmus, diplopia, optic atrophy, and sphincter troubles are among the signs which may be forthcoming. Less commonly, a one-sided affection of the spinal cord above the lumbo-sacral enlargement is due either

to some intramedullary disease, such as a patch of *myelitis*, a *gumma*, or a *new growth*. When this occurs there may arise a symptom-complex to which the term *Brown-Séquard paralysis* is applied. In this condition there is spastic paralysis of the leg on the same side as the lesion, together with loss of sensibility, especially of thermal and painful sensibility, in the opposite leg. The physical signs in Brown-Séquard paralysis are represented in greater detail in the accompanying diagrams (Figs. 469, 470) : —

Zone of hyperaesthesia

Local effects { Atrophic paralysis
Painful and thermal loss
Loss of all reflexes

No local effects

(4 to 6 normal segmental areas)

Spastic paralysis

Not constant { Loss of sense of passive position and movement
Loss of tactile discrimination

Loss of sensibility to painful and thermal stimuli
Loss of tactile and pressure sensibility and localization uncommon

Remote effects { Diminished skin reflexes
Increased tendon reflexes
Ankle-clonus
Extensor plantar reflex

Normal skin reflexes
Normal tendon reflexes
No clonus
Flexor plantar reflex.

Fig. 469. Diagrammatic representation of the results of a one-sided lesion of the spinal cord—Brown-Séquard paralysis.

Hysterical paralysis of one leg usually does not present much difficulty in diagnosis. The affected limb may be either rigid or flaccid : in either case there is no true muscular

Fig. 470. Brown-Séquard paralysis due to an intramedullary one-sided lesion (right) of the lower thoracic cord. The shaded area was insensitive to deep and superficial pain and to all degrees of temperature, but sensitive to touch. The sense of passive movement and position and tactile discrimination were disturbed in the right foot. There was spastic paralysis of the right leg only.

atrophy and no alteration in the muscular response to electrical stimulation. The condition of the reflexes provides the most important information. In the hysterical form of paralysis the knee- and ankle-jerks may be exaggerated, but they are never lost. A true ankle-clonus is never obtained, and the plantar reflex is either absent or of the flexor type. As a general rule the tendon-reflexes in the opposite unaffected limb will be found to be equally brisk. In contradistinction to spastic paralysis resulting from a pyramidal lesion, in which dorsiflexion of the ankle and flexion of the knee are the movements most profoundly affected, the movements of the leg in a case of hysterical paralysis are found to be more or less equally deficient at all joints and in all directions. Certain attitudes and certain types of gait are almost characteristic of hysterical paralysis of one leg. In one form the whole leg is kept rigidly extended, and the foot strongly inverted, so that the patient walks on the outer plantar edge with a stiff leg. In another form the leg is flaccid and is dragged behind the opposite limb with the toes scraping the floor. In some cases examination of the limb when the patient is at rest in bed reveals little or no paralysis, but in the attempt to stand or walk the limb appears to be quite useless. Hysterical paralysis of a leg may of course be associated with similar palsies of the

opposite leg, or of the arm on the same side (hysterical paraplegia, hysterical hemiplegia). More often than not a leg which is the seat of hysterical paralysis also presents complete insensibility to all forms of stimulation, and the upper limit of such anaesthesia may correspond abruptly to some level for which there is no neuro-anatomical basis—to the line of the knee for instance, or the groin, or the umbilicus.

In the early stages of *paralysis agilis* a patient may complain of loss of power in one leg, and the diagnosis may present considerable difficulty if the characteristic tremor of this disease has not made its appearance. Examination of the limb may show little abnormal. Some slight paresis and slight stiffness to passive movements may be detected, but no alteration in the character of the reflexes will be observed. The diagnosis must depend more upon the general aspect and the attitude and gait of the patient. Some loss of facial expression, the general slowness of his movements, and the tendency to shuffle with the affected leg, are points which may lead the observer to form a correct opinion.

Paralysis of the Leg with Muscular Atrophy. In a case which presents atrophic palsy of one leg, the first essential for making a diagnosis is to ascertain the exact distribution of the atrophied muscles, and to review this distribution in the light of what we know with regard to the central and peripheral innervation of the muscles of the lower limb (see tables below and *Fig. 471*).

TABLE SHOWING THE MUSCLES TO WHICH THE VARIOUS NERVES OF THE LUMBAR AND SACRAL PLEXUSES ARE DISTRIBUTED.

Inferior gluteal nerve (L. 5, S. 1, 2)	<div> <div>{ Gluteus maximus</div> </div>

Single-nerve palsies are not so common in the lower extremity as in the upper, but they may occur, especially as the result of injury. Isolated *paralysis of the anterior crural nerve* and of the *obturator nerve* are quite uncommon, and when they do occur are generally the result of compression of the nerve within the abdominal cavity, either by growths or during the act of parturition. In affections of the anterior crural nerve the movements of flexion of the thigh on the trunk and extension of the leg upon the thigh may both be impaired or lost. Wasting of the anterior thigh muscles, and diminution or loss of the knee-jerk, are other obvious signs of this condition. When the *obturator nerve is injured*

the patient can flex his hip but cannot adduct the thigh, and so, when sitting, he can raise his knee but cannot throw it across the other leg. He can walk about with no obvious disturbance of gait, but he cannot rotate the thigh either outwards or inwards with any degree of force.

Paralysis of the main trunk of the sciatic nerve, which would include paralysis of all the muscles supplied by the internal and external popliteal nerves, points to disease or injury affecting the pelvis. It may be brought about by a fracture of the pelvis or of the upper end of the femur, or by injuries to the hip-joint; on the other hand, the sciatic nerve may be compressed by tumours or by inflammatory masses within the pelvis. Such an extensive palsy has considerable effect on the patient's gait, as he is unable to flex the knee, and consequently has to use the leg as a stiff, extended support; the disability is increased by the absence of all movements at the ankle-joint. The sensory loss in such a condition includes the outer side of the leg and the whole of the foot, except a small area on its inner and upper aspect.

Palsy of the *external popliteal nerve* is the commonest isolated nerve palsy in the lower extremity. Not only is it particularly exposed to injury in its course through the popliteal space, and as it winds round the fibula, but a primary neuritis of it is by no means uncommon, especially in cases of diabetes mellitus and lead poisoning. Isolated paralysis of the external popliteal nerve has been observed frequently in *tabes dorsalis*. Its most obvious result is the dropped foot to which it gives rise, and the high-stepping gait which is necessary if the patient is to clear the ground with his toes.

Injury to the *internal popliteal nerve* is much less common, but it may be involved by tumours or the products of inflammation in the upper part of the leg. Paralysis of the calf muscles is the chief consequence, preventing the patient from extending his foot and standing on tip-toe, or from making any springing movement in the attempt to walk or run. The paralysis of the interossei and the unopposed contraction of the long extensors may lead to CLAW-FOOT (p. 140).

In addition to the peripheral-nerve palsies of the lower limb, we have to consider paralysis due to lesions of the roots leaving the lumbo-sacral region of the cord, and forms resulting from disease of that part of the spinal cord itself (see table above). Atrophic palsy of one leg is not commonly the result of *spinal caries*, although it may occur when the caries affects the lower lumbar or sacral region. On the other hand, paralysis of one leg, generally associated with acute pain of root distribution, is not a very rare early symptom of *malignant disease of the lower part of the vertebral column*. In the absence of any obvious deformity the diagnosis in such cases is often difficult, and much may depend on the use of skiagraphy (*Figs. 157, 158*, p. 192; and *Figs. 483, 484*, p. 630) or upon the history of a growth elsewhere which may have been removed, from the breast for instance, even years previously. In some cases a good deal may be learnt from observing loss of the natural spinal lumbar curve, and from a suggestion of shortening in the stature of the patient, and particularly by noticing the diminished interval between the lower ribs and the iliac crests. These are signs of collapse on the part of the softened vertebræ, and constitute a condition to which the name 'entassement' is applied.

Syphilitic meningitis, involving the roots of the lumbo-sacral cord, is another not very uncommon source of crural monoplegia. The diagnosis depends upon the history of syphilis, a positive Wassermann serum reaction, the results of an examination of the cerebrospinal fluid, and the fact that both the motor palsy and the sensory loss follow a root distribution.

Probably more common than any other cause for atrophic paralysis of one leg is the disease known as *acute poliomyelitis* (p. 623).

Tumours of the spinal cord and syringomyelia are very much rarer causes of paralysis of one lower extremity, although the possibility of their occurrence may sometimes need

to be taken into consideration. Various forms of *progressive muscular atrophy*, of either spinal or primary muscular origin, are more important causes of PARAPLEGIA (p. 621) than of unilateral paralysis. As a general rule they are symmetrical, or approximately symmetrical, in their onset and progress, but every now and then one may meet with cases in their earliest stage when the complaint of the

patient is referred to one limb only. A good example is afforded by the case of a lad who was brought to me on account of weakness in one foot, which had appeared quite insidiously and was tending to progress. The

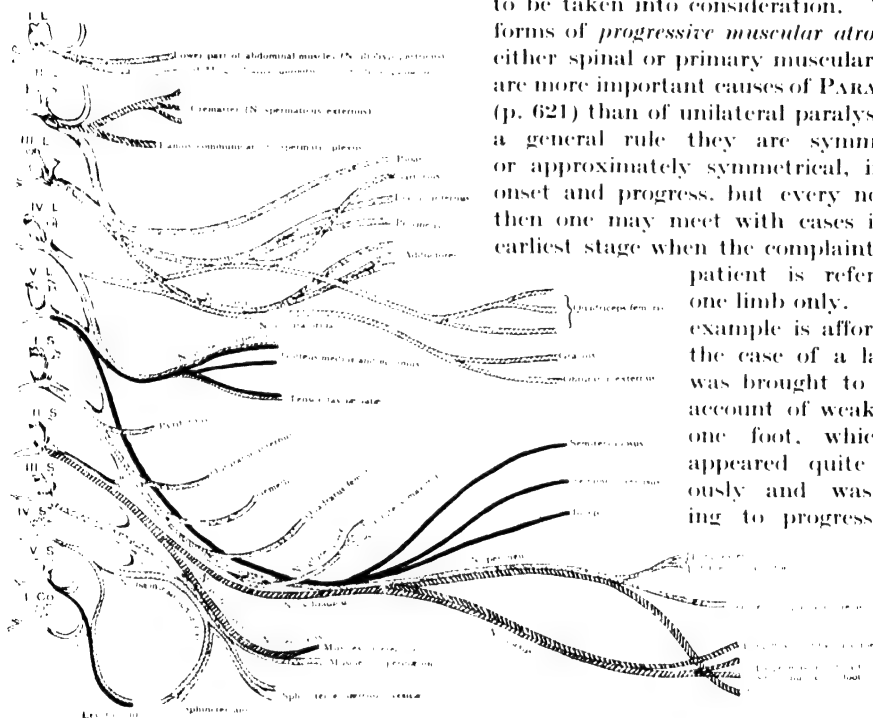

FIG. 471. Diagram to illustrate the lumbo-sacral plexus and its branches (after Kocher).

affected limb showed atrophic palsy of the long extensors of the toes and of the peroneal muscles. The diagnosis of *peroneal muscular atrophy* (p. 78) was confirmed by the appearance of similar physical signs in the other leg some months later. In addition to their early symmetrical distribution, these progressive degenerative diseases can be distinguished from gross diseases of the spinal cord and its envelopments by the absence of pain in the course of their evolution.

E. Farquhar Buzzard.

PARALYSIS OF ONE EXTREMITY (UPPER). The word 'paralysis' has come, by general use, to include partial as well as complete palsies, and to embrace all varieties of impaired voluntary movement. It is in this sense that the word is used for the purpose of this article. No other interpretation would be of value in discussing diagnosis, because the latter depends, not upon the degree of paralysis, but upon its nature, distribution, and associated phenomena. Accurate diagnosis is often most difficult, although perhaps more important from the point of view of successful treatment, when the limitation of voluntary movement is only slight. Before discussing the various forms of paralysis met with in the arm, some reference must be made to a few practical points which are important in the proper investigation of cases complaining of inability to use an arm.

The medical man must not be satisfied with the patient's statement that he has lost power or that he is weak in his limbs. Tests must be employed to ascertain whether this

is really the case. The movements at each joint, of flexion, extension, pronation, supination, must be investigated, and if necessary their power measured against the observer's resistance. It may be found that the grasp is powerful in a patient who is unable to use his hand on account of loss of control over the finger movements. In such a case there is not paralysis, but inco-ordination (see ATAXY, p. 73). Similarly, there is certain to be difficulty in carrying out delicate movements if there is loss of cutaneous or postural sensibility. Without perfect sensibility it is impossible to handle a pen in a proper manner. Sometimes a patient will complain of loss of power, when investigation shows that the ability to execute movements is inhibited by the pain in a muscle or joint evoked by the attempt. In other instances, mechanical limitation of movement by arthritic changes, without pain, may lead the patient to believe that there is loss of power. He finds he cannot lift his arm, and ascribes the disability to paralysis instead of to ankylosis of the shoulder-joint. On the other hand, pain and loss of power may be associated in some forms of neuritis. If the patient says, "My arm is so painful that I cannot lift it," examination must be directed to ascertain whether the inability is due only to painful inhibition or to real paralysis in addition.

Stress must be laid upon the necessity for obtaining a careful history, and especially an accurate account of the duration of the trouble, whether its onset was sudden, rapid, or slow and progressive, and whether the loss of power was accompanied or preceded by pain, numbness, or tingling. The family and previous history must not be neglected. In examining the paralysed arm, care should be taken that the whole of *both* upper limbs, as well as the neck, upper part of thorax, and shoulders, are stripped, so as to be inspected easily and the two sides compared. It will also be necessary, in the large majority of instances, to investigate the functions of the cranial nerves, and the reflexes, etc., of the trunk and lower extremities. This is often imperative even when no complaint is made of loss of power or other symptoms in any part of the body except one upper limb. The importance of this full examination is perhaps obvious, but it may be illustrated by reference to two points. A lesion of one internal capsule may give rise to paralysis of the opposite arm, but it will be likely to cause, in addition, some alteration in the abdominal and leg reflexes of the corresponding side. Similarly, a lesion of the 8th cervical or 1st dorsal spinal segments, or of their corresponding spinal roots, will also affect the fibres leaving the cord at that level and passing, via the cervical sympathetic, to the eye of the same side. In this way atrophic paralysis of the muscles of one hand may be associated with a small pupil and a small palpebral fissure on the same side, a coincidence which at once points to the cord or roots as the site of the lesion, and acquits the peripheral nerves of being concerned in the production of the palsy. In such a case the further investigation of the abdominal reflexes, the knee-jerks, and plantar responses will help to decide whether the lesion is intramedullary or extramedullary; in the former event the abdominal reflexes on the same side would be absent, the knee-jerk would be increased, and the plantar response would be of the extensor type, while in the latter, unless there was considerable pressure on the cord, the reflexes below the arm would be normal.

For purposes of differential diagnosis, brachial palsies may be divided into two main groups: (1) *Those without*, and (2) *Those with muscular atrophy*.

1. PARALYSIS WITHOUT MUSCULAR ATROPHY.

This heading embraces cases in which there may be general impairment of nutrition and perhaps muscular wasting due to disuse, but in which there is no localized muscular atrophy and no alteration in the response of the muscles to electrical stimulation. The cases may be divided into two groups: (1) *Those in which there is some affection of the upper motor neuronic system (pyramidal lesions)*; and (2) *Cases without lesion of the pyramidal tract*.

Paralysis due to Pyramidal Tract Lesions.—The most familiar example of this group is afforded by cases of brachial monoplegia due to a *vascular lesion (thrombosis, hemorrhage, or embolism) in the internal capsule* or other part of the pyramidal tract in its course through the brain. In the diagnosis of this condition the points of importance are: The presence of some cardiovascular condition capable of producing the lesion, such as disease of the heart, kidneys, or arteries; the sudden or rapid onset of the symptoms, with or

without loss of consciousness or other cerebral disturbance. The arm retains its natural contours, and the muscles are not atrophied, although they may appear, after some time has elapsed, to be smaller than those of the other arm. The paralysis may affect the whole limb and include inability to shrug the shoulder; or the movements of the hand and fingers may be more impaired than those of the elbow and shoulder. There is a tendency for the arm to exhibit more and more resistance to passive movement, that is to say, to develop spasticity. At the same time, if left to itself, the limb will adopt a fixed position, which includes adduction of the upper arm to the trunk, flexion and pronation of the forearm, and flexion of the wrist and fingers. If any movements are possible, they will be those of flexion rather than of extension at the various joints. The muscle tone is increased, and the tendon-jerks, such as the ulnar and radial wrist-jerks, the triceps, biceps, and supinator jerks, are exaggerated when compared with those of the opposite limb. Eventually contractures may develop, and it will be found impossible to extend the upper arm, forearm, hand, and fingers into one straight line.

Such is the clinical picture afforded by spastic paralysis of the arm, and one case will differ from another only in the degree of spasm and the degree of paralysis; but the amount of spasticity and the paresis do not always correspond. In one patient the rigidity forms the chief obstacle to voluntary movement; in another the arm, though powerless, shows comparatively little increase in tone.

The fact that the pyramidal fibres destined for the face, trunk, and leg run in close proximity to those for the arm, is sufficient reason for suspecting that, even if no other paralysis is complained of, there may be signs of disturbed function in other parts. The side of the face corresponding to the paralysed arm may not move so quickly or so powerfully as the other side in a voluntary effort to show the teeth, although no difference may be detected when the patient smiles. The corresponding abdominal reflexes may be found wanting. The knee-jerk may be increased; ankle-clonus and an extensor plantar response may be elicited; all on the same side.

This spastic arm, in all degrees of severity, may result not only from a vascular lesion in the brain, but also from a *cerebral abscess*, a *cerebral tumour*, or *cerebral inflammation* (encephalitis). The arm will present identical features, so that the diagnosis must be made from a consideration of other data. Thus a *cerebral abscess* only becomes likely when there is some infective process either in the bones of the skull (e.g., mastoid or frontal sinus disease) or in a distant part such as the heart or lungs (e.g., ulcerative endocarditis or bronchiectasis). Headache, vomiting, and optic neuritis, with a slow pulse, slow respiration, and subnormal temperature, may help in the diagnosis. In cases of *cerebral tumour* the development of the brachial palsy is nearly always slow and progressive, spreading from one part of the limb to another, and again there may be headache, vomiting, and optic neuritis. It should be remembered, however, that these signs of increased intracranial pressure are not always present, and that the presence of a tumour is always to be suspected when a spastic paralysis of one limb comes on in a slow and progressive manner. Some tumours grow at the expense of neighbouring tissues in such a way that pressure is raised but little or not at all. *Encephalitis* will need to be considered when there is a history of acute constitutional disturbance with fever, vomiting, headache, and perhaps convulsions preceding or attending the onset of the paralysis. The latter, however, is not progressive. It reaches its maximum in a few hours, and shows a general tendency to improve after the acute symptoms have passed off. In some cases of epidemic encephalitis the disease is ushered in by an attack of hemiplegia, the arm perhaps being the part chiefly affected.

Disseminated sclerosis is another disease in which a spastic monoplegia is not uncommon. The diagnosis is easy if it occurs late in the disease, when nystagmus, optic atrophy, spastic paraplegia, and sphincter trouble are already present, or if there is a history of previous transient palsies affecting other limbs. When, however, paralysis of one arm is the first symptom, as it may be, the diagnosis may be difficult. The rapid onset of the palsy in a healthy young adult, without constitutional disturbance, severe headache, or vomiting, and perhaps the discovery of absent abdominal reflexes and an extensor plantar response, should direct suspicion to the possibility of a patch of disseminated sclerosis being responsible for the trouble.

Diseases of the pons, medulla, and that part of the spinal cord which lies above the cervical enlargement, whether vascular, inflammatory, or neoplastic, may cause spastic palsy of

the upper limb, but it is rarely a monoplegia. The arm and leg on one side, or both arms and both legs (quadriplegia), are much more likely to be involved simultaneously, and the site of the lesion is inferred from the knowledge that the two pyramidal tracts are in close proximity in those regions.

Paralysis without Lesions of the Pyramidal Tract.—It is not uncommon for a patient in the earliest stage of *paralysis agitans* to complain of loss of power in one arm. This sometimes leads to a wrong diagnosis, the trouble being described vaguely as due to neuritis, or even hysteria. This mistake will be avoided if notice is taken of the fact that the limb is not only weaker than its fellow, but that it is somewhat stiff and conspicuously slow in carrying out movements. A lack of expression in the face, absence of the natural swing of the arm in walking, and a tendency to carry the limb in a flexed position across the trunk, and perhaps some hesitancy in the gait, should guide the observer to a correct diagnosis even if tremor is absent, as it often is at this stage of the malady. This form of paralysis is unattended by changes in the reflexes.

A child suffering from *chorea*, and especially hemichorea, is often brought to the doctor with the complaint that he or she has lost the use of an arm. Examination will show that there is really some weakness of the affected limb, which is demonstrated, not so much by the poorness of the grasp, as by the fact that the child is unable to maintain a steady pressure. He will grasp the observer's fingers, but quickly release the pressure, although urged to continue the squeeze. In the same way, when asked to put out his tongue he will do so, but withdraw it at once. When required to extend his arm in front of him with the palm of the hand facing downwards, it will generally be noticed that the wrist is slightly flexed although the fingers are extended. These are points which may be useful in coming to a right conclusion when choreic movements are not conspicuous; but attention must also be paid to the condition of the heart and to any history of rheumatism. No information of value can be obtained from the reflexes unless perhaps the choreic form of knee-jerk is present (p. 452).

Hysterical brachial palsy may resemble one due to a pyramidal lesion in presenting marked rigidity, or the whole limb may be flaccid and limp. Some general wasting of the muscles may be present, but there is no alteration in their electrical reactions. Organic pyramidal lesions must be excluded by an examination of the reflexes. The supinator, biceps, and triceps jerks may be tried, but they will not be appreciably more brisk than those of the opposite limb. The abdominal and plantar reflexes will be natural. If the limb is rigid the observer will probably be able to overcome the rigidity by steady pressure, and to extend the arm, forearm, hand, and fingers into one straight line. When the patient is asked to perform a certain movement the observer can often see that in the effort to carry it out the antagonistic muscles are put into action rather than, or as well as, those which are necessary for its execution; thus, the triceps will contract as well as the biceps.

If the patient is requested to flex the elbow, with the result that the forearm is moved very little or not at all. This may also be demonstrated when the observer resists the movement of flexion by grasping the wrist and then unexpectedly relaxes his resistance; in an organic palsy this will be followed by further uncontrolled flexion at the elbow, whereas in a hysterical palsy the contraction of the triceps maintains the forearm in its former position. Another important point in distinguishing a palsy of cerebral origin from one which is hysterical is that in the organic case, even when no voluntary movement whatever can be carried out by the fingers, the latter may move involuntarily in association with energetic movements in the opposite limb. Thus, when the patient is asked to grasp some object as tightly as he can with the sound hand, flexion of the fingers may be detected on the paralysed side. The same phenomenon is seen in connection with involuntary movements, such as yawning. The writer remembers being requested to see a case in which there was paralysis of one arm, and in which the diagnosis between organic and functional disease was in doubt. The first question he asked the patient was whether he could open his hand and extend his fingers; the patient replied in the negative, but immediately volunteered the statement that the fingers became extended whenever he yawned. This settled the point in dispute at once, because such associated movements do not occur in hysterical palsies. In many, if not most, cases of hysterical palsy of an arm, the limb is also anæsthetic, and this anæsthesia can generally be recognized as hysterical on account of its complete character. In a cerebral palsy there is nearly always some impairment of

postural sensibility, even if tactile, painful, and thermal sensibility is intact; but the hysterical patient is usually insensitive to all forms of stimulation, even pinching or a strong faradic current. Moreover, the distribution of the anaesthesia does not correspond to any form seen in organic disease, and is frequently of a glove or sleeve type with a very sharp line of demarcation.

2. PARALYSIS WITH MUSCULAR ATROPHY (OR ATROPHIC PALSY).

In this category are included all cases of brachial palsy in which there is true muscular atrophy associated with some alteration in electrical reactions, either the typical reaction of degeneration or quantitative diminution of excitability to galvanic and faradic currents. In all such cases there is some organic lesion affecting some part of the lower motor neurons; there must be some disease involving (1) the spinal segments from the 5th cervical to the 1st dorsal, (2) the corresponding anterior spinal roots, (3) the brachial plexus, (4) the peripheral nerves of the arm, or (5) the muscles themselves.

In addition to atrophy and alteration in electrical response, each paralysed muscle tends to lose its tendon-jerk. For instance, the tendon-jerk of an atrophied biceps cannot be obtained, and in all probability direct percussion of the muscle itself will also fail to elicit a contraction, or will give rise only to an abnormally slow contraction. Muscles which are undergoing atrophy may also exhibit fine fibrillary contractions of a spontaneous kind, but these are seen only when the disease affects the nerve-fibres, and not when the muscles themselves are affected primarily. These fibrillations are very rarely seen in the group of muscular atrophies to which the name of 'myopathy' is given.

When making a diagnosis of the site of the lesion in cases of atrophic brachial paralysis it is essential to analyse carefully the distribution of the atrophied muscles. This must be done in order to answer the questions: Are all the atrophied muscles supplied by one peripheral nerve, or are they innervated by one or more spinal segments, or by one or more anterior spinal roots? The diagnosis will be comparatively simple when it is found, for instance, that all the atrophied muscles are supplied by the musculospiral nerve, and that all the muscles supplied by that nerve are atrophied and paralysed. A lesion of that nerve can then be diagnosed and its nature inferred from other data, such as the use of a crutch or the history of a fractured humerus with callus involving the nerve at the site of the fracture.

Let us now consider briefly some of the various conditions giving rise to atrophic palsy of the upper extremity, and the features which are most characteristic for diagnostic purposes.

In cases of *neuritis* there may be paralysis of the muscles supplied by one nerve only, or of muscles supplied by several nerves (multiple neuritis). In the former case the correct diagnosis of the lesion depends on a knowledge of the muscles innervated by each of the chief brachial nerves, and this may be gleaned from the following table (see also *Fig. 474*):

TABLE OF MUSCLES TO WHICH THE NERVES OF THE BRACHIAL PLEXUS ARE DISTRIBUTED.

<i>Nerve.</i>	<i>Muscles.</i>	
Posterior scapular (C. 5)	(Levator anguli scapulae Rhomboides minor	Rhomboides major
Long thoracic (C. 5, 6, 7)	Serratus magnus

When several nerves are involved in neuritis the condition is one of *multiple neuritis*, and, being generally due to some toxic cause, tends to be bilateral and symmetrical. Multiple neuritis is further characterized by the facts that the peripheral muscles are more affected than the proximal, that the extensors of the wrist and fingers suffer out of proportion to the flexors, and that there are often pain and tenderness in the paralysed muscles. These features are present in *alcoholic neuritis*, the most common form (p. 85). In *lead*

palsy the extensors of the wrists and fingers are particularly susceptible, although other muscles supplied by the musculospiral nerve such as the supinator longus and the triceps may escape altogether. The association of dropped wrist with a blue line on the gums, and other signs of plumbism (p. 45), is diagnostic of this form of brachial palsy. In some cases of multiple neuritis it is impossible to identify the causative toxin, but glycosuria, mercury, and arsenic, in addition to alcohol and lead, must be remembered in this connection. Leprosy may produce a precisely similar condition (Fig. 472), but it is rarely met with in Great Britain. (See also *Atrophy, Muscular*, p. 78.)

In most cases of single-nerve palsy the diagnosis, based on the distribution of the muscular atrophy and paralysis with altered electrical reactions, can be confirmed by the detection of sensory loss in the cutaneous area supplied by the same nerve. In other cases the sensory fibres appear to offer more resistance than the motor to the exciting cause of the neuritis, and little or no disturbance of sensibility can be found. (For areas supplied by the peripheral nerves, see Fig. 584, p. 751, and *SENSATION, SOME ABNORMALITIES OF*, p. 747.)

Reference may be made to one or two of the single-nerve palsies which present special points in relation to diagnosis.

In *paralysis of the serratus magnus* (Fig. 473) due to injury or neuritis of the *long thoracic nerve*, the patient may complain of general weakness of the arm, and particularly of inability to raise it above the horizontal position. The trouble arises from the fact that the scapula is no longer held against the thoracic wall, and cannot be rotated with the movements of the limb. The origin of this disability may be overlooked if the arm only is examined. If, however, the position of the scapula is observed when the arm is moved in different directions, the correct diagnosis can be arrived at. When the arm hangs at rest by the side, the scapula is seen

Fig. 472. Paresis of the arms due to peripheral neuritis in an arrested case of lepra maculo-anæsthetica in a Norwegian. (From a photograph by the late Dr. Hansen, Inspector-General of Leprosy in Norway.)

to be slightly raised and displaced outwards, with the inferior angle inclining towards the vertebral column and perhaps somewhat separated from the chest wall (*Fig. 473*). When the arm is raised forward to the horizontal position and pressed against some resistance, the inner border of the scapula projects backwards and presents a 'winged' appearance. This deformity ought always to suggest paralysis of the serratus magnus.

Fig. 473. Photographs illustrating the deformities produced by palsy of the right serratus magnus. It is often associated with weakness of the lower trapezius fibres, and is found most commonly in carpenters and sawyers.

The movements of the upper limb are also hampered somewhat in cases of neuritis or injury to the *suprascapular nerve*, and the patient may complain of difficulty or fatigue in writing. Examination will show flattening of the infraspinous fossa and weakness in rotating the humerus outwards against resistance. The infraspinatus may show the reaction of degeneration, but the supraspinatus is not accessible, being covered by the trapezius.

Adhesions within the shoulder-joint, with secondary wasting of the deltoid, may simulate paralysis in the distribution of the *circumflex nerve*, owing to the difficulty in abducting the arm; but a little care in examination and electrical testing of the deltoid muscle will suffice to make a diagnosis. In circumflex palsy, moreover, some sensory loss may be found in the skin over the upper and outer aspect of the arm.

In cases of *musculospiral paralysis* the injury to the nerve may be above or below the points where branches leave to supply the triceps and supinator longus muscles, and these muscles may therefore escape. Sensory symptoms are often absent, but some anaesthesia is sometimes found on the radial border of the hand.

In connection with traumatic affections of the *median nerve*, the distribution of the paralysis depends on the site of the wound; the branch which supplies the muscles of the hand may leave the main nerve in the forearm, and thus escape injury when the wound is at the wrist.

Paralysis of the ulnar nerve is discussed in the article on CLAW-HAND, p. 141.

Ischemic paralysis of the hand (Volkmann's contracture—*Fig. 151*, p. 178) must not be forgotten in cases of injury to the forearm when there is a history of the patient wearing a splint, and the condition must not be mistaken for ulnar or median paralysis. The diagnosis depends partly upon the history, but chiefly upon the rigid contracture of *all* the flexor tendons of the wrist and fingers, with wasting of the muscles and other trophic changes. The electrical excitability of the flexor muscles is sometimes impaired.

Paralysis of one arm due to a *lesion of the brachial plexus* is a common event, the most frequent cause being some injury. When the whole plexus is damaged, complete brachial palsy, with atrophy of the muscles and extensive sensory loss, results. The diagnosis of such a lesion is simple, because it would be impossible for the spinal cord to be damaged sufficiently to bring about such a paralysis without giving rise to symptoms of atrophic

palsy in the opposite arm, and spastic paralysis, with disturbances of sensibility, in the trunk and legs.

In addition to a lesion of the brachial plexus as a whole, two forms of partial palsy are not uncommon, and have received special names. The first is known as *Erb's palsy*, and is due to a lesion of the upper trunk of the brachial plexus, composed of fibres from the 5th and 6th cervical roots. The paralysed muscles include the spinati, deltoid, biceps, supinator longus, and to a less extent the extensors of the wrist and fingers. The arm hangs by the side, and the forearm remains pronated owing to weakness of the supinator muscles, and especially of the biceps. There is sometimes, but not always, anaesthesia over the outer aspect of the forearm and hand. This form of palsy is usually produced by a fall on the shoulder of such a kind as to separate the latter forcibly from the head, and so to exert sudden and severe traction on the upper part of the brachial plexus. A similar lesion is often seen in infants as a result of injury during birth, and has been called *Duchenne's palsy*, after the observer who first described it. In both Erb's and Duchenne's palsy, the grouping of the paralysed muscles resembles that which may follow an injury to the 5th and 6th cervical segments of the spinal cord, but in the latter case bilateral symptoms are practically certain to be present, as well as more extensive disturbances of

sensation of the trunk and limb, probably of the dissociative type. (See SENSATION, SOME ABNORMALITIES OF, p. 747). In spinal-cord lesions, moreover, we may see an atrophic paralysis of the muscles supplied by the 5th and 6th cervical segments, together with a spastic paralysis of the remaining muscles in the arm—that is to say, of the muscles innervated from the 7th and 8th cervical and 1st dorsal segments. This mixture of atrophic and spastic paralysis in the upper limb can only be brought about by some injury or disease of the spinal cord.

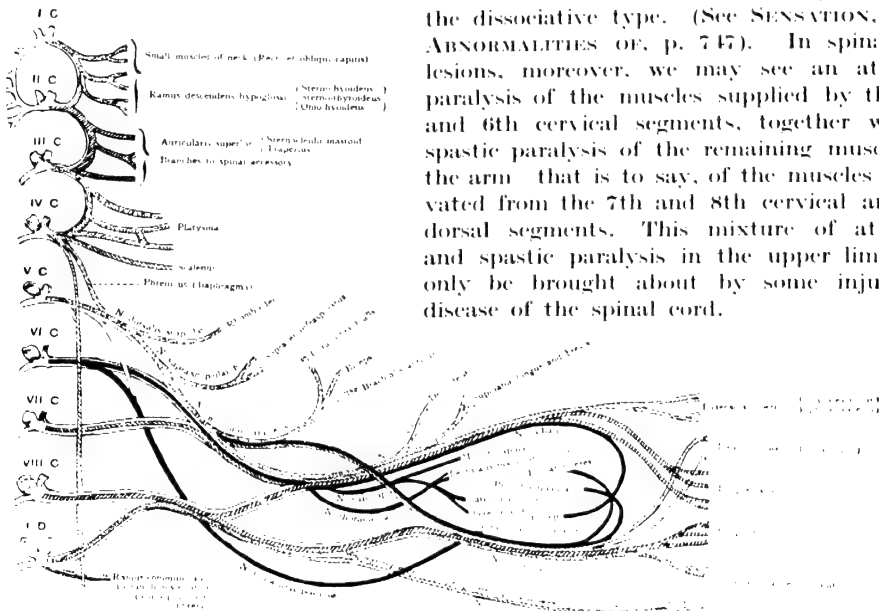

Fig. 171.—Diagram to illustrate the cervico-brachial plexus and its branches. (after Kocher).

The other form of partial brachial plexus palsy, *Klumpke's palsy*, depends on a lesion of the trunk formed by the 8th cervical and 1st dorsal roots. The flexors of the wrist and fingers, and the intrinsic muscles of the hand, undergo atrophy, and although the patient can carry out all movements at the shoulder and elbow, he is unable to move his fingers. The area of anaesthesia in this form involves the ulnar border of the forearm and hand from the elbow downwards. This condition may be distinguished from a spinal-cord lesion affecting the 8th cervical and 1st dorsal segments, not only by its limitation to one upper extremity, but also by the absence of the oculo-pupillary symptoms which are nearly always present in spinal lesions of that level: a lesion of the spinal segments in that region, or of the corresponding spinal roots in their intravertebral course, produces a diminution in the size of the pupil and a narrowing of the palpebral aperture on the same side. Such a pupil does not dilate to shade, nor when the skin of the neck is pinched, nor when a cocaine solution is dropped into the eye. Although the presence or absence of oculo-pupillary symptoms affords a point of differentiation between lesions of the 8th cervical and 1st dorsal segments of the spinal cord, or of their corresponding roots on the one hand,

and a lesion of the lower trunk of the brachial plexus on the other, in the majority of cases, yet in very severe injuries to the neck the lower roots of the plexus may be actually torn away from their connection with the spinal cord, in which case the oculo-pupillary symptoms mentioned above will be present.

Amyotrophic lateral sclerosis is a condition dependent on a gradual degeneration and disappearance of the anterior cornual cells of the spinal cord, associated with sclerosis of the upper motor neuron tracts. The muscular atrophy begins insidiously and progresses gradually. It often begins in the intrinsic hand muscles (Aran-Duchenne type), less commonly in the shoulder and upper arm muscles. The loss of power is in proportion to the amount of atrophy. The alteration in electrical reactions is usually more a quantitative diminution of excitability to both currents than a true reaction of degeneration. Fibrillary contractions are common. The atrophy usually begins in one limb before the other, but soon becomes more or less symmetrical. The tendon-jerks of all muscles which are not atrophied are exaggerated. The abdominal reflexes may be absent, and the plantar reflexes may be of the extensor type. There are no pains, no sensory loss, and no oculo-pupillary phenomena.

In *syringomyelia* the spinal changes frequently begin in the cervical enlargement of the cord, with the result that atrophic paralysis is first noticed in the upper extremity, generally in the intrinsic muscles of the hand and the flexor muscles on the ulnar aspect of the forearm. The onset is insidious and the progress gradual. One limb is generally affected many months, perhaps years, before the other. Manual deformities are common (see CLAW-HAND, *Fig. 124*, p. 142). The electrical reactions vary like those of amyotrophic lateral sclerosis. The knee- and ankle-jerks are increased as a rule, and spastic paralysis of the lower extremities usually develops in the later stages, with extensor plantar responses. Pains shooting down the arms occur, but are not common. Trophic changes develop in the skin, subcutaneous tissues, and joints. There is sensory loss of a dissociative type, i.e., loss of sensibility to pain, heat, and cold, with preservation of tactile sensibility. Oculo-pupillary phenomena and nystagmus are common. Spinal curvature, in the form of a dorsal scoliosis, is another frequent physical sign. It is not necessary that all these signs and symptoms should be present for making a diagnosis. The combination of muscular atrophy, dissociative anaesthesia, and trophic changes in the skin is usually sufficient.

A *cervical rib* may be responsible for atrophic palsy in the upper extremity. Paralysis is usually preceded by pain, chiefly referred to the inner aspect of the arm, and sometimes shooting into the little and ring fingers. The pain is worse after exertion, and often relieved by placing the hand behind the head. Muscular atrophy begins in the hand muscles (*Fig. 475*), the interossei, thenar, and hypothenar eminences, and often involves the flexors of the wrist and fingers. It develops gradually and does not spread beyond the distribution just described. There is often sensory loss in regions corresponding to the cutaneous areas supplied by the 1st dorsal and 8th cervical spinal roots. The loss is usually less marked to touch than to painful and thermal stimuli. The atrophied muscles show reaction of degeneration. There are no oculo-pupillary phenomena and no signs of disease in other parts of the body. The condition is usually one-sided, occasionally bilateral: the chief diagnostic point is the discovery of the ribs by skiagraphy (*Figs. 440, 441*, p. 544). At the same time it must not be concluded that the absence of a rib shadow in an X-ray photograph is in all cases a contra-indication to the diagnosis: a ligamentous band, undetected by the skiagraphic examination, is sometimes found to occupy the position of a supernumerary rib and to be responsible for similar results in the way of pain and atrophic palsy. (See also PAIN IN THE EXTREMITY, UPPER, p. 543; and CLAW-HAND, p. 141.)

Fig. 475.—Atrophic palsy of right hand associated with long 7th cervical rib of that side. Note the marked wasting of the abductor pollicis as compared with the other muscles of the thenar eminence. According to S. A. K. Wilson this is a common feature of these cases, but it is not pathognomonic. (*By Dr. P. W. Saunders.*)

Another disease in which atrophic palsy of the intrinsic hand muscles is a prominent feature is *peroneal atrophy*. As the name suggests, the muscular atrophy and paralysis generally begin in the lower, before they affect the upper, extremities, and further details concerning the condition may be found under ATROPHY, MUSCULAR (*Figs. 81 and 82, p. 79*), and PARALYSIS OF ONE EXTREMITY, LOWER, p. 611.

The diagnosis of muscular atrophy in the arm dependent on a preceding *acute poliomyelitis* (*Fig. 80, p. 78*) is not difficult if an accurate history can be obtained. The onset was acute, with constitutional disturbance, varying from a transient and perhaps overlooked malaise to a pyrexia up to 104° F., with generalized pains all over the body, possibly vomiting, or even convulsions. It is almost invariable that the initial paralysis was more extensive than that which remained permanent. Attention to the distribution of the paralysis shows that it is irregular and different in every case, but there is more liability on the part of the shoulder and upper arm muscles to suffer than those of the forearm and hand. If both arms are affected there is little likelihood of any great degree of symmetry in the distribution of the atrophy. With regard to the electrical reactions, much will depend on the stage at which the case comes under observation. Some muscles may show the reaction of degeneration, others may respond fairly well, and others show no response whatever to either faradism or galvanism. Vasomotor changes, general defects in the growth of the limb, deformities, and contractures are common, but no sensory changes and no oculo-pupillary phenomena are to be observed. Only those reflexes are altered or lost which are concerned with atrophied muscles.

Hæmorrhage into the spinal cord, or *hamatomyelia*, due to injury, occurs more often at the level of the 8th cervical and 1st dorsal segments than at any other. The resulting paralysis has much the same distribution as that described in Klumpke's palsy (p. 618), but the diagnosis may be made from the fact that the former also produces spastic paralysis of the trunk and legs, and frequently gives rise to areas of dissociated anaesthesia. Oculo-pupillary phenomena are usual as well in cases of hamatomyelia at this level. Injuries to the cord result in bilateral symptoms, whereas Klumpke's palsy is confined to one arm.

Various forms of root palsies may be caused by *tuberculous or malignant disease of the vertebrae*, and also by *pachymeningitis*, frequently syphilitic. The diagnosis of the nature of such lesions depends on examination of the vertebral column and of the cerebrospinal fluid. The symptoms are more often bilateral than unilateral, and may be complicated by the results of pressure on the spinal cord, leading to spastic paralysis of parts below the level of the disease.

Tumours originating in the meninges or in the spinal cord at the level of the cervical enlargement are rare, but they may produce atrophic paralysis of the arm muscles, with spastic paralysis of the trunk and lower extremities. These phenomena may be more marked on one side at first, but tend to become bilateral with the gradual growth of the tumour.

In the group of diseases to which the name *myopathy* or *muscular dystrophy* is applied, the arm is often more or less completely paralysed. The diagnosis of this condition depends on a consideration of various factors. The gradual onset and the bilateral symmetry of the affection, the marked involvement of the shoulder and upper arm as compared with the forearm and hand, are important characteristics. The absence of fibrillary contraction and of the reaction of degeneration are also to be noted, while the history of a similar affection in other members of the family, and the presence of muscular atrophy or muscular pseudo-hypertrophy in other parts of the body, serve to confirm the diagnosis.

TABLE SHOWING THE MUSCULAR DISTRIBUTION OF THE VARIOUS NERVE-ROOTS OF THE BRACHIAL PLEXUS.

Those muscles which are the most useful landmarks for individual segments are printed in italics.

- | | |
|-------|---|
| C. 5. | <i>Deltoid, Spinati, Teres minor, Rhomboids, Diaphragm, Biceps, Supinator longus, Serratus magnus, Pectoralis major, Brachialis anticus, Coracobrachialis.</i> |
| C. 6. | <i>Biceps, Coracobrachialis, Brachialis anticus, Supinator longus, Deltoid, Spinati, Teres major, Serratus magnus, Pectoralis major, Subscapularis, Pronators of forearm, Extensors of wrist.</i> |
| C. 7. | <i>Triceps, Extensors of wrist and fingers, Pronators of forearm, Pectoralis major, Subscapularis, Latissimus dorsi, Teres major.</i> |
| C. 8. | <i>Flexors of wrist and long flexors of fingers, Interossei and lumbricales, Muscles of thenar and hypothenar eminences.</i> |
| D. 1. | <i>Muscles of thenar and hypothenar eminences, Interossei and lumbricales, Flexor carpi ulnaris, Oculo-pupillary fibres.</i> |

A glance at this table shows that nearly all muscles derive innervation from more than one spinal segment, generally from two or three. The table does not purport to give a complete anatomical list of all the muscles of the arm, but provides a guide to clinicians in their endeavours to localize spinal or root lesions from the distribution of atrophic muscular paralysis (see also *Fig. 474*).

E. Farquhar Buzzard.

PARAPLEGIA implies partial or complete paralysis of both legs, with or without part of the trunk. It does not, however, include inability to walk owing to mechanical defects, such as old fractures, joint disease, and so forth; it is due, as a rule, to changes either in the brain, the spinal cord, the peripheral nerves, or in the muscles themselves, though sometimes it is caused by errors of function without any structural change in the neuro-muscular system. For clinical purposes, although naturally a paraplegia that has arisen in childhood may persist into adult life and thus cause overlapping of the classification, paraplegia in children may be discussed separately from paraplegia in adults. Let us suppose that the patient is a child, and that the chief complaint is weakness or paralysis of both legs. The following table indicates some of the causes that may produce this condition:

I. THE CAUSES OF PARAPLEGIA IN CHILDREN.

- A. Conditions in which there is no definite local disease, though there may be some general pathological condition:* (1) Simple delayed walking; (2) Rickets; (3) Cretinism; (4) Idiocy.
- B. Paraplegia associated with a definite upper neuron nerve lesion:—*
 1. Infantile diplegia due to: (a) Congenital defect of the cortex-porencephalus; (b) Infantile encephalitis; (c) Injury, for example by forceps at delivery; (d) Superior longitudinal sinus thrombosis; (e) Meningitis; (f) Congenital or acquired hydrocephalus.
 2. Congenital malformation, such as meningocele, spina bifida, or spina bifida occulta.
 3. Spinal caries, with compression of the spinal cord.
 4. Friedreich's ataxy.
- C. Paraplegia due to a lesion of the lower neuron type:—*
 1. Acute anterior poliomyelitis, leading to infantile paralysis.
 2. Tooth's peroneal type of progressive muscular atrophy.
 3. Peripheral neuritis.
- D. Paraplegia of the primary muscular type:—*
 1. Pseudo-hypertrophic muscular paralysis.
 2. The infantile type of primary muscular dystrophy.
 3. The juvenile type of primary muscular dystrophy.
- E. Paraplegia due to poisons or toxins:—*
 1. Tick paralysis.

In arriving at the diagnosis, the first point to pay attention to is the history; the case will belong to one or other of two main groups, the first containing those that have never been able to use the legs properly, the second those that have lost the use of the legs after having been at one time able to walk, or at least move them efficiently.

To the first group belong all cases of congenital malformation, such as *hydrocephalus* or *meningocele*, and most cases of *infantile diplegia*. Before diagnosing any of these, however, it is necessary to exclude *rickets*, *cretinism*, *idiocy*, and *simple delayed walking*, as causes of an apparent rather than a real paraplegia. These cannot be the sole diagnosis if there is absolute flaccidity on the one hand, or if there is spasticity on the other. It is important to remember how deceptive the reflexes may be; almost any illness in an infant or young child—bronchopneumonia, for example, or simple diarrhoea—may so depress the knee-jerk that it is often unobtainable until the patient's general health is restored; the plantar reflex is normally often extensor in infants; ankle-clonus, however, does not occur except when there is degeneration of the lateral columns. If there is neither absolute flaccidity nor spasticity, and if the limbs are moved spontaneously, the mere fact that the child is late in walking by no means necessarily indicates nerve disease; the

delay may commonly extend to the second year, and occasionally even to the third, fourth, or fifth, especially in hypothyroidic cases who are often equally backward in talking and in general intelligence. The main factor in making a diagnosis in such a case is time, for, until with the lapse of time the little patient begins to walk, it may sometimes be difficult to exclude organic paraplegia. If there are definite signs of rickets, or if the patient is a cretin or an idiot, the diagnosis is more obvious. The good effects of giving thyroid extract over a prolonged period may be the only conclusive means of distinguishing cretinism from idiocy, and this remedy should be employed in all such cases, however hopelessly idiotic the infant may seem to be (*Fig. 476*). If there is congenital optic nerve atrophy and blindness the case is one of idiocy and not cretinism.

Having excluded the above, the next thing to consider is whether there is any congenital malformation of the brain or cord. Cases of *meningocele*, *myelocoele*, or *spina bifida* will generally be obvious enough: even *spina bifida occulta* will often suggest itself from the presence of a pigmented or hairy mole over the lower part of the lumbar spinal region,

Fig. 476. Cretin mistaken for Mongolian idiot.

and the diagnosis may be confirmed by careful palpation there. Congenital *hydrocephalus* makes itself evident from the characteristic enlargement of the head, which in extreme cases can be mistaken for nothing else, and in lesser degrees can be distinguished from the enlargement due to rickets or to congenital syphilis by the fact that it is more uniform, and that the bones are fragile and thin and separated at the sutures. The chief doubt that arises in a case of infantile hydrocephalus is as to whether it is truly congenital or was caused by an early but post-natal posterior basal meningitis. Many of these cases are not really congenital: the head is not large at birth, but the enlargement follows a febrile illness, with or without convulsions—a meningococcal meningitis.

Congenital defect of the cortex would suggest itself as the cause of infantile diplegia in a case in which delivery had taken place without difficulty and without the use of forceps, the head and spine not being hydrocephalic or deformed, and yet with the limbs paralysed from birth: they may be flaccid or they may be spastic, and there is no constant type of reflex, though there is a tendency to increased knee-jerk, ankle-clonus, and extensor plantar reflex. Intelligence will very likely be defective at the same time. In rare cases the kidneys may be so large and cystic that they can be

palpated, and the brain may then be cystic also—*porencephalus*.

Paraplegia due to *injury at birth*, either by the use of forceps or by excessive compression in a contracted maternal pelvis, is a diagnosis that can only be made when there has been an unusual amount of difficulty at birth, for it is remarkable to what extreme degrees the child's head may be squeezed and altered in shape without apparent detriment. Seeing that it is the lateral aspects, especially the arm areas of the Rolandic cortex, that will be most affected by forceps, these instruments are more likely to cause bilateral arm paralysis than ordinary paraplegia. Just the converse of this is true of *superior longitudinal sinus thrombosis*, for the leg areas of the brain lie close up against either side of this sinus, whilst the arm areas, being more distant from it, are likely to be less affected. The symptoms of superior longitudinal sinus thrombosis, of *acute encephalitis*, and of *meningitis*, may be so similar—pyrexia, general head symptoms, vomiting, and convulsions—that it is almost a matter of guess-work to choose between them when they are actually in progress; if death occurs in a few days, suppurative meningitis is likely; if in a few weeks, tuberculous meningitis; if the patient lingers for many weeks before dying, or if recovery occurs with hydrocephalus, posterior basal or cerebrospinal meningitis; if recovery occurs without hydrocephalus, it may be almost impossible to decide between meningococcal meningitis, acute encephalitis, and superior longitudinal sinus thrombosis;

nor is the distinction material, except in so far that it is important to remember always that a favourable issue may occur even in a case that seems to be hopelessly comatose and dying—a diagnosis of meningitis may have been made erroneously when the condition was really one of acute encephalitis only. If it seems to be of great importance to arrive at the accurate diagnosis in the acute stages, it may be justifiable to perform lumbar puncture or even puncture through a fontanelle or into the cisterna magna; cytological examination of the cerebrospinal fluid so obtained may show polymorphonuclear cells in a suppurative or meningococcal case, lymphocytes in a tuberculous case; whilst the casual organisms may be found bacteriologically, either on direct examination of stained films or after cultures have been made from the fluid.

If one is able to exclude the infantile diplegias, and the conditions which simulate them, the probability is that the patient will have shown obvious signs of being able to use the legs, or may even have been able to walk, before the paraplegia set in. In that case, if the paralysis is of the upper neuron type, with spasticity, no wasting except such as may be due to disuse and non-development, no reaction of degeneration, increased knee-jerks, extensor plantar reflexes, ankle-clonus, and probably bladder and rectal trouble—especially if there is anaesthesia in the legs at the same time—by far the commonest cause for the condition is tuberculous *spinal caries* with compression of the cord.

If, on the other hand, the patient develops a lower neuron type of paralysis, with wasting of the affected muscles and reaction of degeneration, the chances will be greatly in favour of *acute anterior poliomyelitis* followed by infantile paralysis, particularly if diphtheria can be excluded, and if a clear history can be obtained that the child was perfectly well until he developed an obscure febrile complaint, taken for influenza, perhaps, or acute rheumatism, until it was noticed that one or more limbs, possibly all four, had become limp and paralysed. In one type of the disease—*Landry's acute ascending paralysis*—a fatal ending occurs rapidly owing to involvement of the phrenic centres in the cervical enlargement of the cord when the paralysis has, as it were, swept continuously upwards from the feet to the legs, and thence to the trunk, arms, and neck. More often the fever subsides in a few days, and there may be great improvement in the paralysis during the next few weeks. It is possible for a child to have had absolute paralysis of all four limbs from acute anterior poliomyelitis and yet make a complete recovery: more often, however, one or another group of muscles remains weak; in a typical case, the extensors of the toes and ankles are affected permanently, the consequent contraction of the unparalysed calf muscles leading to talipes equinus or equinovarus. Weakness of other groups of calf muscles leads in a similar way to other forms of club-foot, such as T. calcaneus, T. valgus, and so on. In other cases, the muscles below the knee recover completely, but some other group is involved—the quadriceps extensor femoris, for instance, or the adductors of the thigh. It is of course possible for the legs to recover completely, whilst paresis of some group of muscles in the shoulder, arm, or forearm persists. The infantile paralysis which follows acute anterior poliomyelitis is nearly always asymmetrical, but it is by no means necessarily so, and it may cause persistent partial paraplegia. It is important to remember that the knee-jerk is deficient or absent only when the quadriceps extensor femoris muscle is affected; and also that reaction of degeneration is no longer obtainable in the muscles when the disease is of sufficiently long standing for all the degenerate fibres to have become fibrous, by which time the only muscle- and nerve-fibres that remain are normal, though they are fewer in number than they should be.

Peripheral neuritis in a child is decidedly uncommon except as the result of *diphtheria* or of the giving of *arsenic* in large or long-continued doses in the treatment of such affections as *chorea*. Being an affection of the lower neuron type, with wasting of the muscles, flaccidity, reaction of degeneration, and deficiency in the tendon reflexes, it may be difficult to distinguish from acute anterior poliomyelitis. It might be urged that the occurrence of pain or other sensory symptoms is in favour of peripheral neuritis and against poliomyelitis, but this is not really the case; the inflammation in poliomyelitis is by no means necessarily restricted to the grey matter of the anterior cornua, and the acute stage of the disease is often accompanied by severe pains referred to the peripheral parts. There may, however, be bacteriological or other evidence of the patient's having had diphtheria during the preceding few weeks, in which case peripheral neuritis would be diagnosed; if there is paresis of the soft palate, as evidenced by the regurgitation of fluids through the nose

when the patient tries to swallow them, or by the nasal character of the voice, diphtheritic neuritis would be probable.

As regards Friedreich's ataxy, Tooth's peroneal type of progressive muscular atrophy, and the primary muscular dystrophies, particularly pseudo-hypertrophic muscular paralysis, two points are common to all: they all are insidious in onset, slowly progressive for years before the end comes as the result of an intercurrent malady; and they are familial diseases, the family history having an important bearing upon the diagnosis.

Friedreich's ataxy is characterized by paraplegia, often associated with deformity, such as talipes and scoliosis, owing to persistent error of posture, without wasting except such as may be due to disuse or non-development: the knee-jerks are absent, but the pupils react normally; there is no sphincter trouble unless quite late; ankle-clonus is absent, but there is generally a remarkable condition of hallux erectus, which amounts to a permanent extensor plantar reflex: there are no sensory disturbances; the arms may not be affected, or they may present some degree of ataxy, with or without intention tremors—that is to say, tremors which are increased when the patient tries to perform voluntary movements—sometimes even choreiform movements are present; speech is

monotonous, nystagmus is sometimes present, and occasionally there is optic atrophy. If progressive paraplegia develops at about 8 or 9 years of age in a child with a family history of similar trouble; if the knee-jerks are absent, whilst the big toes are permanently erect; and if there is neither atrophy nor pseudo-hypertrophy of the muscles, the diagnosis is in all probability Friedreich's ataxy. The patient may survive to adult life, but is liable to death from phthisis, pneumonia, or other intercurrent malady—the same applying to all the familial diseases now under discussion.

Tooth's peroneal type of progressive muscular atrophy is apt to develop after some simple specific fever, such as whooping-cough or measles. The first point the mother notices is that the child hitherto normal is unable to bend the big toes upwards; a condition of permanent plantar flexion of the big toes ensues; inability to extend the other toes follows; and presently the patient cannot dorsiflex the ankles. It is chiefly the muscles supplied by the external popliteal nerve, formerly called the *peroneal* nerve, that are affected; hence the name of the disease. Talipes may result. The lesion is not primarily in the muscles, but in the anterior cornual cells of the lumbosacral part of the cord, so that reaction of degeneration is obtainable in the wasted muscles. The knee-jerks remain normal so long as the quadriceps extensor femoris is unaffected, there is no ankle-clonus, and the big toe

Fig. 177. Pseudo-hypertrophic muscular paralysis, exhibiting the Herculean type of pseudo-hypertrophy of the calves. (By kind permission of Dr. Patterson, of Newcastle-on-Tyne.)

may not move at all when the sole is stimulated. A brother or a sister is very likely to have suffered from the same complaint (see Figs. 81, 82, p. 79).

In the *primary muscular dystrophies* the nerves are normal, so that there is no reaction of degeneration; if a muscle has become entirely atrophied there will be no reaction in it at all; but as long as any reaction is obtainable it is of the normal type. The same applies to the reflexes. The most easily recognized of all the primary muscular dystrophies is pseudo-hypertrophic muscular paralysis, the only difficulty being when no family history is obtainable, and when the case is still in too early a stage to be typical. Boys are affected more often than girls, but it is generally inherited from the mother's side. It is possible for some members to have presented atrophic myopathy, whilst others suffer from the pseudo-hypertrophic form. When fully developed the most striking feature of the case is the marked weakness of the legs, notwithstanding the apparent firmness and great size of the calves (Fig. 477). The muscles are really atrophied, their apparent enlargement being due to extensive deposition of intramuscular interstitial fat. Ultimately, if the patient survives, all the muscles in the body become wasted and fibrous;

but whereas some of them atrophy from the first, others exhibit marked pseudo-hypertrophy before they atrophy—particularly the gastrocnemii, the solei, the glutei, the deltoids (*Fig. 478*), the supra- and infra-spinati, and portions of the triceps. The muscles of the hands and feet are generally unaffected. The muscles which are most frequently atrophied are the lower half of the pectoralis major, the latissimus dorsi, the serratus magnus, the biceps, and the flexors of the knee. There are no sensory or sphincter troubles. When the case is well advanced, the way in which the patient gets up from a lying posture is very characteristic: it is generally described as 'climbing up himself'. He first rolls over and rests on his hands and knees: then puts his head between his arms and raises the knees from the ground, so that he is now supported on his hands and feet: he next brings one hand nearer to his toes, and then, swinging his body over first to one side, places his opposite hand on the corresponding knee, straightens that leg, and repeats the performance on the other side, so that he now stands with his legs widely separated and with a hand resting on each knee: he then works each hand alternately higher up his thighs, until finally, by a sudden backward movement of his shoulders, he attains the erect attitude. Another feature of the case is that if one tries to lift the boy up by putting one's hands under his armpits, his shoulders rise right up to his ears, and he very easily slips through one's hands. He is also unable to stand on tip-toe, and the gait is waddling.

The two other types of muscular dystrophy mentioned on p. 621—the infantile and the juvenile—are but different varieties of the same malady: both are characterized by progressive wasting of the muscles without pseudo-hypertrophy: in the infantile form the muscles have been atrophic from the first, whereas in the juvenile form the muscles develop in what seems to be a normal way up to a certain point, and then gradually waste away. The disease is distinguished from peripheral neuritis by: (1) The absence of reaction of degeneration: (2) The persistence of the reflexes as long as any muscle tissue is left to respond: (3) The family history: (4) The absence of sensory changes: and (5) The absence of improvement with time. An attempt is sometimes made to classify the primary muscular dystrophies into different kinds according to the groups of muscles first affected. In the Landouzy-Dejerine type, for instance, the face muscles are

Fig. 478. A case of pseudo-hypertrophic muscular paralysis in a man of 49. The figure shows: (1) Drooping of the shoulders from weakness of their upholding muscles: (2) Pseudo-hypertrophy of both deltoids: (3) Atrophy of the upper-arm muscles.

Fig. 479. *Dermacentor venustus*, male and female, 4.th ed.
(Specimen kindly supplied by Lieut.-Col. MacArthur, R.A.M.C.)

attacked first, the trouble spreading slowly to the shoulder and upper arm. It is probable, however, that whatever groups of muscles may be the first affected, the differences are those of degree and type rather than of kind, and that the muscular wasting, wherever it may begin, ultimately becomes widespread, and finally involves all of the muscles more or less.

Tick paralysis is not known in England, but it is met with in Canada, the United States, parts of Africa, and probably elsewhere overseas. It seems likely that more than one variety of tick can cause the trouble, but the best known is the *Dermacentor venustus* or wood tick of Canada (*Fig. 479*). It lives on the sage-brush, gets on to the clothes of human beings, works

its way to the neck or head, and buries itself amongst the scalp hairs with its nose deep in the skin. Its bite is not felt: adults do not suffer materially: but a child becomes drowsy, develops paralysis of the legs, and will die in a day or two unless the tick is hunted for, found, and removed, when the paralysis generally clears up and the patient makes a speedy recovery.

II. THE CAUSES OF PARAPLEGIA IN ADULTS.

It is clear that a paraplegia that has arisen during infancy or childhood may persist into adult life, in which case the diagnosis will be made upon the lines indicated above. It is also possible for some of the causes of paraplegia that usually affect young patients not to do so until they have grown up—compression of the cord by Pott's disease of the spine, for instance. The chief causes, however, for paraplegia arising for the first time in adult life are as follows:—

A. Causes of the lower neuron type of paraplegia:

1. Peripheral neuritis, which may be due to various different causes (p. 82)
2. Anterior poliomyelitis
3. A pelvic tumour interfering with the lumbo-sacral plexus
4. A tumour affecting the cauda equina
5. Compression of the lumbar enlargement of the cord.

B. Causes of the upper neuron type of paraplegia:

1. Transverse myelitis—
 - a.* Primary
 - b.* Due to compression by: (i) Spinal caries: (ii) New growth in the vertebrae or meninges: (iii) Injury: (iv) Aortic aneurysm: (v) Actinomyces of the vertebrae: (vi) Hydatid cyst of the spine
2. Disseminated sclerosis
3. Amyotrophic lateral sclerosis
4. Primary lateral sclerosis
5. Ataxic paraplegia
6. Combined sclerosis of the cord
7. Syringomyelia
8. Meningitis
9. Haemorrhage into the cord
10. Cerebellar tumour or abscess
11. Bilateral cerebral softening or haemorrhage
12. An after-effect of encephalitis lethargica.

C. Causes not conforming either to the lower or to the upper neuron type:

1. Tabes dorsalis
2. General paralysis of the insane
3. Landry's paralysis
4. Functional paraplegia
5. Malingering.

The first points which call for attention in making a diagnosis are the history and progress of the case. In only a few of the above conditions is the onset sudden: these are certain cases of acute anterior poliomyelitis, transverse myelitis, meningeal haemorrhage, Landry's paralysis, functional paraplegia, and malingering. If the paraplegia is of sudden onset, of the upper neuron type, and not the result of injury, it is almost certainly due to some form of transverse myelitis. The great majority of cases of paraplegia, however, have an onset that is not absolutely acute, and generally it is quite gradual.

There are certain conditions that can, as a rule, be either diagnosed or excluded at once. If the patient has Argyll Robertson pupils and no knee-jerks, *tabes dorsalis* can be diagnosed at once. It is necessary to remember, however, that the pupil may react neither to light nor to accommodation in some cases of peripheral neuritis, so that, if care be not exercised, the reaction may be mistaken for the Argyll Robertson type of tabes, the latter being diagnosed when peripheral neuritis is the lesion really present. The converse mistake is also possible, especially if the actual strength of the leg muscles be not tested: in both conditions there may be patches of impaired sensation, but in peripheral neuritis with absent knee-jerks there are absolute wasting, loss of power, and reaction of degeneration, whilst in tabes there is no trophic wasting, and often no great loss of power

in individual muscles, though the patient may complain of weakness in the legs owing to the action of opposing muscles being inco-ordinate, with wasteful use of muscle force and consequently ready fatigue : there is no reaction of degeneration.

Another difficulty in connection with *tabes dorsalis* arises in anomalous cases in which either the pupil reaction has not yet become typical, or else the knee-jerks are not yet gone. If the reaction of the pupil is of the Argyll Robertson type *tabes* may sometimes be diagnosed even in the presence of knee-jerks if there is an obvious history of other concomitants of the disease, such as lightning pains, gastric crises, or any of the rarer crises—laryngeal, rectal, urethral, vesical, renal, general abdominal, or sweating—marked ataxy, history of syphilis, perforating ulcer of the foot, a Charcot's joint, or bladder or rectal trouble, particularly if the patient is a male who has had much brain wear. The tendo Achillis jerks disappear before the knee-jerks do, and they should be tested carefully. There is also in many cases a remarkable deficiency or even complete absence of deep tenderness in the leg-muscles (*myalgia*) and in such organs as the testis, tongue, larynx, or mamma. In certain cases the knee-jerk may still be obtainable on one side after it has been lost upon the other, so that both should always be tested and not one only.

If the paraplegia is obviously of the lower neuron type, with deficiency or absence of the superficial and deep reflexes, atrophy of the muscles, and reaction of degeneration, with or without paresthesia, the probabilities are that it is due to one of the many different causes of *peripheral neuritis* that are discussed on page 82. If the onset has been sudden, however, and if the paralysis began to clear up again rapidly, except possibly in one group of muscles in one leg, there would necessarily be a suspicion of *acute anterior poliomyelitis* which occurs occasionally in adults.

It is important in all cases of suspected peripheral neuritis to make a rectal examination, lest there be some pelvic mass, malignant or otherwise, interfering with the lumbosacral plexus. Peripheral neuritis may also be simulated closely by either a tumour or a gumma interfering with the cauda equina, an uncommon condition that suggests itself if there is severe pain referred to the lower part of the spinal column behind, or if the paraplegia comes on in such a way as to affect one leg before the other, the pelvis being found free from growth. It is also important to remember that transverse myelitis due to lesions which, if they are situated a little higher up in the cord, cause a paraplegia of the upper neuron type, produces wasting, reaction of degeneration, and loss of reflexes when they affect the cord at the level of the lumbar enlargement.

When the paraplegia is definitely of the upper neuron type, with spasticity of the legs without wasting, with increased knee-jerks, extensor plantar reflexes, ankle-clonus, and perhaps retention of urine with overflow and incontinence of feces, the first step in arriving at the diagnosis is to determine if there is any sensory disturbance at the same time. The only diseases mentioned under heading *B* that produce obvious sensory disorders are transverse myelitis, syringomyelia, hemorrhage into the cord, and very rarely meningitis or bilateral cerebral softening. The latter can only be diagnosed when there has been an apoplectic seizure associated with hemiplegia, followed after an interval by another cerebral seizure which, by producing hemiplegia of the opposite side to the one first involved, results in paraplegia, or rather diplegia. The arms and face are likely to be affected as well as the legs, and there will be either a history of syphilis to account for endarteritis and thrombosis in a young male, or a bruit, a history of acute rheumatism, or other evidence of a heart lesion, to account for embolism : or senile changes, with or without albuminuria, a high blood-pressure, retinitis, and other signs of renal and arterial degeneration, to account for hemorrhage.

Hæmorrhage into the cord is hardly ever spontaneous : it may follow an injury, such as a bullet wound or a stab in the back, and then the history will indicate the diagnosis. *Acute meningitis*, whether tuberculous, suppurative, posterior basal, or cerebrospinal, seldom causes complete paraplegia until a late stage of the illness is reached, by which time the nature of the malady will generally be indicated by the cerebral symptoms, particularly headache, vomiting, convulsions, strabismus, and ophthalmoscopic changes such as optic neuritis or choroidal tubercles. Bacteriological investigations of the fluid obtained by lumbar puncture may assist the diagnosis materially. There is a chronic form of meningitis, however, of which the diagnosis is not so easy, and that is the *chronic hypertrophic hæmorrhagic pachymeningitis* which affects chiefly the vertex and the cervical portion of

the cord. The condition is generally caused by chronic alcoholism in syphilitic subjects, especially if there has also been some injury: the diagnosis is difficult, but it may be suggested by the history, and by the degree of pain referred to the nerves that are involved in the meningeal thickening the chief difficulty being to exclude spinal caries in cases involving the cord. Wassermann's reaction may be positive if no antisymphilitic remedies have been employed: but it may be negative in the blood though positive in the cerebro-spinal fluid, so that lumbar puncture may be called for. In *syringomyelia* a very slowly progressive disease that is by no means always associated with paraplegia: the nature of the symptoms depends upon the degree to which the central canal of the cord and the gelatinous substance around it are affected, also upon the level in the cord at which the changes occur. The diagnostic symptom is that, in some region or another, the skin will be found to have lost its power of distinguishing heat from cold, and pain from touch, though it still retains ordinary cutaneous sensibility. It is apt to give rise to skin lesions in

the parasthetic parts (Morvan's disease), also to acute painless swelling of the joints, with deformity from destruction of the ends of the bones (Charcot's joints (Figs. 345-350, pp. 433, 434) similar to those that may occur in tabes dorsalis.

If the patient has marked impairment of all kinds of sensation in both legs, with paraplegia of the upper neuron type, and no paralysis of the arms, the lesion is almost certainly *transverse myelitis* of some kind. The absence of sensory disturbance, however, does not exclude transverse myelitis, for when the conductivity of the spinal cord is interfered with, without being entirely inhibited, the sensory columns are able to transmit impulses longer than the pyramidal tracts, so that paralysis appears before anaesthesia. The same applies to a transverse myelitis that is getting better, the patient recovering sensation in his legs before he is able to move them. The chief difficulty will be to determine the nature of the transverse myelitis. There are two main types: (1) That due to causes outside the cord compressing it—especially *spinal caries*,

Fig. 480. Skiagram showing early tuberculous caries of the 1st dorsal and of the first two lumbar vertebrae. There was no spinal curvature, but there was pain in the back and local rigidity. The atrophy of the body of the 1st lumbar vertebra is pronounced, and the body of the 2nd lumbar vertebra is swollen-looking and ill defined. There is probably some tuberculous disease of the 3rd lumbar vertebra also.

secondary *growth*, the effects of such *injuries* as fractures of the spine, bullet wounds and stabs, or more rarely erosion of the bones by an *aortic aneurysm*, *actinomycosis*, or *hydatid disease*; and (2) That due to softening from thrombosis of a spinal artery, the result of *syphilis*, or a fever such as *enteric* or *scarlet*. One of the first points to attend to is the presence or absence of pain. Lesions, such as thrombosis, which affect the cord but not its posterior nerve roots, are painless, whereas swellings which compress the cord from without almost always produce pain, sometimes a typical girdle pain, on account of their irritating the posterior nerve roots. If, therefore, there is or has been any pain in the back other than what may be due to a known injury, it is probable that transverse myelitis is not primary but due to compression. If the spine presents an obvious Pott's curvature, or if the patient has other evidence of peripheral tuberculosis, such as enlarged or cascading glands in the neck, disease of the hip, knee, or other joint, a psoas abscess, lupus vulgaris, and so on, especially in a young person who has been in the habit of drinking much milk, compression by *spinal caries* is fairly certain. The main difficulty arises when the cord becomes compressed without deformity of the spinal column, and with no other tuberculous lesion apparent. Local tenderness over one or more vertebral spines will help to suggest the diagnosis, especially if local pain is complained of in the

same region, and if the pain is increased by any jarring of the spine. *Growth* is fortunately much rarer, and is to be excluded by a routine examination of all the viscera, most cases of spinal new growth being secondary to a neoplasm elsewhere, especially of the breast; primary growths of the spine are so rare that they are generally taken for caries at first, and the correct diagnosis is not always arrived at before post-mortem microscopical examination has been made. X-ray examination of the vertebrae may help in detecting either tuberculous or cancerous disease (*Fig. 480*), but it is important to take the plates in the oblique as well as in the antero-posterior positions before excluding gross disease of the vertebral bodies: sometimes the skiagram looks nearly normal in a fore-and-aft picture, and yet marked disease is seen in the oblique position (*Figs. 481-484*). *Aortic aneurysm* is a still rarer cause of compression myelitis: if there is a distinct pulsatile tumour along the course of the aorta, the nature of the case may be obvious; more often, however, an aneurysm which erodes the vertebrae sufficiently to bulge into the spinal canal

Fig. 481. Skiagram from a case of tuberculous spinal caries taken in the anteroposterior axis, and giving the impression that all the vertebrae are normal. (Compare with *Fig. 482.* (By Dr. R. E. Roberts.)

Fig. 482. Skiagram from the case of tuberculous spinal caries seen in *Fig. 481*, taken in the lateral position. This shows definite tuberculous disease of the front of the upper part of the body of the 3rd lumbar vertebra. (*Figs. 481 and 482* illustrate the fact that tuberculous spinal caries may be missed if skiagrams are not taken laterally as well as anteroposteriorly. (By Dr. R. E. Roberts.)

does not at the same time enlarge forward to produce a tumour that can be recognized easily by palpation. The patient will generally be a man in the prime of life who has had syphilis, who is not a life abstainer, and who has worked hard: Wassermann's reaction may be positive. Apart from a pulsatile tumour the symptoms will be very like those of paraplegia from spinal caries. *Actinomyces* of the spine is very rare: it simulates tubercle or new growth until the actinomycotic foci discharge through spontaneous sinuses in the skin, and then the diagnosis is made on the discovery of ray-fungi in the discharge. *Hydatid cyst* of the spine is rarer still, at any rate in England: it would suggest itself if the patient were known to have hydatid disease of the liver or peritoneum: otherwise it would generally be mistaken for tubercle or new growth.

The relationship of *injury* to transverse myelitis is not always quite straightforward. If, for example, a patient who has syphilitic endarteritis of his spinal vessels receives a kick in the back from a horse, he may find that, by next day, he is unable to move his legs; it may at first seem obvious that the kick has been the sole cause of the paraplegia, when

the real cause is syphilis the kick having been the final factor which led to thrombosis in a diseased spinal artery. Transverse myelitis due to *syphilis* is exactly comparable in its mode of origin to the hemiplegia which results from endarteritis obliterans in a middle cerebral artery. There is no pain and no deformity of the spine, but in other respects the paraplegia presents the same features as does that which is due to compression of the cord. Syphilis is by far the most important cause of this primary transverse softening, but there are a considerable number of other maladies in which a similar result ensues occasionally : almost any *infective disease* may lead to it : one may perhaps mention typhoid fever, scarlet fever, and influenza in particular. In infective endocarditis there may be an additional factor, namely, embolism of the cord, though this is decidedly rare.

If it is found that the arms are affected as well as the legs, it is unlikely that the lesion is transverse myelitis, unless in rare and anomalous cases such as those mentioned on page 81. If the onset has been slow, the course progressive, and wasting is present, with

Fig. 183. Skiagram of the spine, taken in the anteroposterior axis, in a case in which there was secondary carcinoma of the body of the 3rd lumbar vertebra : to illustrate the fact that negative findings in an X ray picture of the spine, even in one axis only, may lead to the diagnosis being missed. Incidentally, the skiagram also showed several opacities due to old calcified tuberculous glands within the abdomen, lateral to the spine, as indicated by the arrows. (By Dr. J. H. Mather.)

Fig. 181. Skiagram of the spine from the same case as Fig. 183, taken laterally, showing a small but definite deposit of secondary carcinoma in the front of the body of the 3rd lumbar vertebra : to illustrate the point that the new growth in the spine may be seen in a skiagram taken laterally, when it is not seen in a skiagram taken in the anteroposterior axis. (By Dr. J. H. Mather.)

reaction of degeneration in the muscles of the hands or arms, with increased knee-jerks, ankle-clonus, and extensor plantar reflexes, but no anaesthesia, the malady is almost certainly *amyotrophic lateral sclerosis*.

If there are increased knee-jerks, extensor plantar reflexes, ankle-clonus, ataxy, intention tremors in the hands, nystagmus, and a hesitancy in the voice, which may even be of the type describes as 'scanning', the disease is either *cerebellar abscess or tumour*, or *disseminated sclerosis*. If headache and vomiting have been severe, the former is the more probable, and the diagnosis may be clinched by finding double optic neuritis. Abscess will be more likely than tumour if there is otorrhœa or pyrexia. It is not uncommon to find optic atrophy, with either concentric diminution in the fields of vision or else a central or paracentral scotoma, in disseminated sclerosis, but optic neuritis is uncommon. The difficulty in diagnosing disseminated sclerosis arises mainly when the complaint is in the early stages : the patches of sclerosis may be anywhere in the cord, and before the affected fibres atrophy there is a period when they are sometimes able to conduct impulses, sometimes not ; when they are not able to conduct, there are numerous symptoms, and in a day or two, when conducting power recovers, these symptoms are

gone again; this variation from day to day nearly always leads to a diagnosis of neurosis for months or years before the true nature of the malady becomes obvious. In some patients a central scotoma may develop early, leading to peculiar symptoms, such as the inability to distinguish a sovereign from a shilling if the light is not good, or the liability to run into people without seeing them when cycling. If ataxy is marked, the staggering gait may lead to a suspicion of alcoholism; the patient staggers alternately to either side in disseminated sclerosis, whereas with tumours of one cerebellar hemisphere the tendency is to stagger constantly to the same side. Bladder and rectal troubles are not common in either case, and yet they may be prominent. Paresis may also develop in disseminated sclerosis, although as a rule there is no sensory disturbance at all.

If a patient has the symptoms of spastic paraplegia and ataxy, without anaesthesia, nystagmus, or changes in the voice, a diagnosis of *ataxic paraplegia* will usually be made. There is really no difference between this and what has been called *combined sclerosis of the cord*: in both conditions there is degeneration of the posterior columns, the crossed pyramidal, and the cerebellar tracts. Some observers use the term combined sclerosis only for syphilitic cases, reserving ataxic paraplegia for similar non-syphilitic cases. It is a curious fact that there is complete absence of free hydrochloric acid from the gastric juice (achylia gastrica) in many cases of combined sclerosis of the cord, some of which later develop pernicious anaemia.

Primary lateral sclerosis was a relatively common diagnosis until it was found that the more careful the examination the greater was the likelihood that more than simple degeneration of the crossed pyramidal tracts would be found. Partial compression of the cord produces spastic paraplegia without anaesthesia, and thus simulates primary lateral sclerosis as described above. Disseminated sclerosis may do so likewise, and so on. Primary lateral sclerosis should never be diagnosed, therefore, till all the other affections in which the lateral columns may be affected have been excluded. There is such a disease as primary lateral sclerosis, however: it is generally syphilitic in origin, and it leads to typical spastic paresis of the legs, with increased knee-jerks, ankle-clonus, extensor plantar reflexes, no wasting, no R.D., no sensory disturbances, and, in the later stages, retention of urine with overflow, and incontinence of faeces; the disease is generally progressive, but after reaching a certain point it may remain stationary for years, or even improve to a slight extent for a time. When lateral sclerosis is yet in an early stage a valuable sign of it is the disappearance of the abdominal reflexes.

The diagrams (Figs. 485, 486) may be of assistance in locating the level of the cord at which a lesion may be present.

Fig. 485. Diagram of sensory localization in the spinal cord.

Fig. 486. Diagram of the localization of reflex centres in the spinal cord.

Encephalitis lethargica is protean in its characters, the most constant being the sleepiness or actual coma, which may last for days or weeks; it depends upon which parts of the brain are most involved by the inflammatory changes, and which parts are so damaged as to fail to recover their vitality if the patient survives, what the permanent after-effects are going to be—idiocy, strabismus, facial paralysis, brachial monoplegia, and so on. A rare permanent after-effect is paraplegia of upper neuron type; the diagnosis depends upon recognition of the malady in its acute phase, the paraplegia being the result of destruction of pyramidal cells in both sides of the motor cortex during the earlier phases of the acute cerebral malady.

The causes of paraplegia that remain for discussion are Landry's paralysis, general paralysis of the insane, functional paraplegia, and malingering.

Landry's paralysis is probably not a distinct entity, but rather a very acute type of perhaps more than one variety of paraplegia. It is rare. It affects young adults, who, hitherto strong and well, become rapidly affected by paralysis which starts in the legs and quickly ascends to the trunk and arms, and may even involve the neck and cranial nerves. It either gets well quite rapidly, or else kills the patient in a few hours or days by affecting the intercostal muscles and diaphragm, with consequent asphyxia. There may be slight pains in the affected parts shortly before paralysis sets in, but sensory symptoms are generally slight, or absent. The nature of the malady is obscure, but if one regards it as a very acute and widespread anterior poliomyelitis one accounts both for its main symptoms, its rapid fatality in some cases, and its equally rapid recovery in others. The patient either dies or recovers so quickly that there is no time for the development of muscular wasting or reaction of degeneration.

Paraplegia in cases of *general paralysis of the insane* does not arise until the third stage of that malady is reached; by that time the diagnosis is generally obvious; the paraplegia is part of a general and extreme weakness, and the patient is bedridden.

Functional paraplegia and *malingering* should never be diagnosed until all organic causes—particularly disseminated sclerosis and spinal caries—have been excluded. Malingering may be suggested by the particular circumstances of the case—the patient may be a nervous, self-conscious girl who desires to attract sympathy, or an out-of-work who wants to get a night's shelter in a hospital; careful observation generally leads to the detection of the fraud. Functional paraplegia is less easy to be sure of, and in many patients that which may at first be regarded as functional ultimately turns out to be organic; this is especially true in the case of disseminated sclerosis. The muscles remain of good bulk as they do in the upper neuron type of paraplegia, but although the knee-jerks may be unduly brisk, the plantar reflexes remain flexor, and there is no maintained ankle-clonus. If there is anæsthesia the distribution of the latter is sometimes obviously functional; it may, for instance, start sharply at the knee and cease suddenly at the ankle, or in some other way indicate that it corresponds neither to the segments of the spinal cord nor to the distribution of the peripheral nerves. It is by anomalies of this kind, which make it impossible to fit in the case with any organic lesion, that functional paraplegia is diagnosed by a process of exclusion.

Herbert French.

PARASITES, INTESTINAL. *Tape-worms.* The commonest symptom of the existence of a tape-worm is the passage of the detached terminal segments per rectum

FIG. 487. Part of a tape-worm (*Taenia solium*), a little smaller than actual size.

in longer or shorter tape-like strips (Fig. 487). The only condition for which these

might be mistaken is muco-membranous colitis, in which long, narrow, white mucous casts of the bowel may be passed with the motions (see *Fig.* 386, p. 495). It may be easy to distinguish these, however, if the suspected material is floated in water, for in the case of a cast of the bowel a central lumen may be found which is not present in the tape-worm. There is, moreover, no regular segmentation in the case of muco-membranous colitis, whereas tape-worms are obviously segmented. If any doubt remains, examination with a lens will show the glandular structure of the uterus in the tape-worm segments, and no such structure in the strips of mucus in muco-membranous colitis. It is sometimes stated that picking of the nose and a voracious appetite are symptoms of the presence of some kind of intestinal parasite; but this is hardly ever the case: if constitutional symptoms develop at all, they take the form of deficiency of appetite, with more or less anaemia, which may become profound: there is often considerable Eosinophilia (p. 271). The three forms of tape-worm that occur in the human intestine are *Tania solium*, *T. mediocanellata*, and *Bothriocephalus*

Fig. 488. Head of *Tania solium* (cemiclia granumata). ($\times 30$.)

Fig. 489. Head of *Tania mediocanellata* (cemiclia canaliculata). ($\times 30$.)

(From Cunningham's 'Fishes of Children and Adults'.)

Fig. 490. Head of *Tania echinococcus* showing four sucking discs and thirty-four hooklets, alternately long and short. (Medium power.) (From a specimen in the possession of Mr. Pellscher, New Bond Street, W.)

hooklets in a single row (*Fig.* 488); the head of *T. echinococcus*, the short tape-worm of the dog, and the source of hydatid cysts in man, also has hooklets, but these are thirty-four in number and in two rows, alternately longer and shorter (*Fig.* 490). The head of *T. mediocanellata* has four circular sucking discs and no hooklets (*Fig.* 489); whilst that of the *Bothriocephalus latus* has a flattened oval head, with two elongated lateral sucking discs and no hooklets (*Fig.* 491). The degree of anaemia, chlorotic in type, is usually greatest

that occur in the human intestine are *Tania solium*, *T. mediocanellata*, and *Bothriocephalus latus*, the commonest in Great Britain being the *T. mediocanellata*, the cystic stage of which is spent in cattle. *T. solium* is derived chiefly from pig-meat, whilst *Bothriocephalus latus* occurs mainly in those who live much on fresh-water fish. It may be possible to make the diagnosis of *T. mediocanellata* by holding the segments up against a bright light and seeing a median streak or water-channel, in addition to one down either edge of each strip, this middle water-channel giving the name to the parasite. The ultimate proof of the nature of the tape-worm, however, is afforded by the characters of the head, that of *T. solium* having four sucking discs, with a rostellum surrounded by about twenty

Fig. 491. *Bothriocephalus latus*. A, Head (natural size). B, Lateral view ($\times 15$). C, Dorsal view ($\times 15$). (From Cunningham's 'Fishes of Children and Adults'.)

with *Bothriocephalus latus*, least with *T. mediocancellata*, and the same also applies to the degree of eosinophilia. The eggs of the tape-worm are unmistakable (Fig. 492): they are spherical, with a dark-brown central portion, and a lighter striated broad capsule.

Fig. 492. Ova of *Tania solium*, semidiagrammatic. (High power.)

Microscopical Examination of Faeces. One of the best ways of preparing faeces for microscopical examination for the ova of parasites, or for other solid particles, is to put about as much as would cover a shilling into a test-tube, filling the latter two-thirds full of normal saline solution ($1\frac{1}{4}$ dr. of salt to a pint of water), corking the tube, and shaking it vigorously in order to break up the faeces as much as possible; on allowing to stand for twenty minutes, the upper part of the fluid remains opaque with fine debris, whilst the heavier particles, including the ova of parasites, have sunk to the bottom: the supernatant opalescent or opaque fluid may now be poured off, and the more definite residue again shaken up with normal saline and allowed to stand for another twenty minutes: this process is repeated until the supernatant fluid becomes clear after it has stood for the twenty minutes, and then, when as much of the fluid as possible has been poured away, a drop of the sediment is taken up in a pipette, transferred to a microscope slide, covered, the excess of fluid removed with filter paper, and the specimen examined either with the $\frac{3}{4}$ -in. or $\frac{1}{2}$ -in. objective, preferably with the mechanical stage. Such a specimen exhibits all sorts of vegetable cells, keratin particles, and so forth, which may at first be regarded as ova, but when the actual ovum of an intestinal parasite is seen, there is seldom any doubt about it.

Round-worms. The only round-worm that occurs in man in Great Britain is the *Ascaris lumbricoides*. This parasite may or may not give rise to symptoms: if it does so, they take the form of slight and obscure nervous and gastro-intestinal disorders. More often the diagnosis is quite unsuspected until one of the worms is found in the bed, having crawled out per anum, especially when the patient, usually a child, falls ill of some febrile malady. If round-worms have been found previously, and if the existence of others is suspected, the diagnosis may be confirmed by discovering the typical ova (Fig. 493) in the faeces; their chief characters are their relatively

Fig. 493. Ova of *Ascaris lumbricoides*. (High power.)

large size, oval shape, and irregular membranous envelope outside the chitinous shell. This worm does not produce eosinophilia as a rule, but in exceptional cases it may do so.

Thread-worms. *Oxyuris vermicularis*, if present at all, usually occurs in hundreds, and

Fig. 494.—Thread-worms, magnified about four times.

can be detected immediately by examination of the faeces with the naked eye. Each parasite is rather less than $\frac{1}{4}$ in. in length, without any colour (Fig. 494); the extremities project from the faecal mass, and move about slowly, like

Fig. 495. Whip worms (*Trichocephalus dispar*) in the caecum and ascending colon. (From a specimen in the Gordon Museum, Guy's Hospital.)

threads waving in the air. These parasites produce no eosinophilia. The patients are nearly always children, and there may be no symptoms at all; but more often there is considerable irritation around the anus, and in young girls about the vulva. Gonorrhœa has before now been suspected when the vulvar infection was really due to the *Oxyuris vermicularis*.

The *Whip-worm* (*Trichocephalus dispar*) is in itself an entirely unimportant parasite occurring in the cæcum and large intestine (Fig. 495), and producing no symptoms whatever. The worm with its tail is about $1\frac{1}{2}$ in. in length, and it is often coiled up watchspring-wise. Its appearance is unmistakable; its ovum (Fig. 496) looks more or less like a running-cork, and, with its deep brown central parts and clear ends, it is quite characteristic. Whip-worms are present to the extent of nearly 10 per cent of all the inhabitants of some cities. They produce no eosinophilia, blood-changes, or symptoms.

FIG. 496.—Ovum of *Trichocephalus dispar*. (Herb. French.)

The *Hook-worm* (*Ankylostomum duodenale*) (Fig. 497). This is not a general parasite in Great Britain, but has affected many persons in certain districts as the result of introduction from abroad, particularly amongst lead-miners in Cornwall. Outbreaks also occurred in the workers in the St. Gothard tunnel, and the disease is prevalent in many parts abroad, especially in India, Egypt, Brazil, and Jamaica. The infection is carried from faeces to soil, from the soil to the hands, thence to the mouth, and so to the alimentary canal. The symptoms are for the most part those of progressive anaemia and asthenia, inability to continue with work, oedema of the lower extremities, anasarca, shortness of breath, and the occurrence of boil-like skin eruptions, described popularly as the 'flowers' of the disease. The appearance of the patient may suggest pernicious anaemia, and the blood-count may sometimes seem to confirm this diagnosis at first; for whereas a great many of the patients have a severe chlorotic type of anaemia, some have a marked reduction of the red corpuscles and a slightly less reduction of the hæmoglobin, so that there is a high colour-index such as is characteristic of pernicious anaemia. There is generally no leucocytosis, but the differential leucocyte-count may suggest the diagnosis at once, for nearly all the patients present a considerable degree of eosinophilia. The administration of anthelmintics such as thymol or carbon tetrachloride may lead to the evacuation of the mature worms, which may be recognized in the faeces (Fig. 97, p. 102), each being from $\frac{1}{4}$ to $\frac{3}{4}$ in. in length. The ova (Figs. 98 and 99, p. 103) are oval, with a clear transparent shell and coiled-up embryo parasite. Melæna is another symptom which may be prominent in some of these cases.

FIG. 497.—*Ankylostomum duodenale*. (From a specimen in the Gordon Museum, Guy's Hospital.)

The two intestinal parasitic affections which produce the most serious anemias and other toxic effects in man are *Ankylostomum duodenale* and *Bothriocephalus latus*.

PERISTALSIS, VISIBLE. The importance of visible peristalsis lies in the fact that it is always pathological except in a few cases in which its unimportant nature is immediately obvious. The three chief conditions which render the normal movements of the bowels visible are *divarication of the abdominal recti muscles*, *ventral herniation of a laparotomy scar*, and *extreme thinness of the abdominal parietes*, the result of emaciation, or of innate poverty of musculature, or congenital absence of the recti abdominales. The first of these is best detected when the recumbent patient, who is generally a multiparous woman with a soft flabby abdomen, tries to raise her head and thorax from the couch without the use of her arms: the contracting recti come together then, and close over the gap in the middle line in which, under the stretched and unsupported skin, the bowel movements had been seen. The other two are generally obvious at first sight. In almost all other circumstances visible peristalsis is pathological: it may then be divided into two types—gastric, and intestinal.

Gastric Peristalsis takes the form of a comparatively large swelling in the upper part of the abdomen, coming and going, generally appearing from under the region of the left ribs, progressing slowly downwards and to the right, where it fades away and disappears: it corresponds more or less with the greater curvature of the stomach. It is often stated that a return wave, passing along the lesser curvature from right to left, can also be made out, but this is exceptional. Sometimes, instead of progressing, it comes and goes almost in the same spot, varying in shape but scarcely in position. The exact site of the wave must depend mainly upon the size and position of the stomach. It indicates *pyloric* or *duodenal obstruction*, and its presence serves to exclude atonic gastrectasis. There may or may not be other signs of dilated stomach, particularly a widely distributed succussion splash, vomiting of large volumes of fermenting fluid at relatively long intervals, and a greatly increased bismuth X-ray shadow with bismuth still in the stomach eight hours after the meal. Whether the pyloric stenosis is simple or malignant has to be decided upon other grounds.

Visible Intestinal Peristalsis is, with the limitations discussed above, one of the surest signs of grave intestinal obstruction. There are almost certain to be abdominal distention, vomiting, and constipation along with it, and the discussion of the differential diagnosis of the different causes of these symptoms will be found elsewhere. The great importance of visible peristalsis is seen in those doubtful or obscure cases in which the patient seems hardly ill enough to be suffering from intestinal obstruction. It may be thought that colic, the result of some indigestible article of diet, is a more likely diagnosis, and that a dose of castor oil will cure the malady. Rather than wait for increasing severity of the symptoms to clinch the diagnosis in these cases it is important to arrive at an early diagnosis of the necessity for laparotomy if life is to be saved. If the small intestine alone is involved the waves are multiple, and they run more or less transversely across the abdomen—the ladder-rung type: when the colon is obstructed, vertical waves, especially in one or both flanks, are the chief form the peristalsis takes. Definite and visible peristalsis is, so far as any single sign can be relied on, an almost infallible indication of the need for laparotomy in any case in which the other symptoms and the history point to a possibility of intestinal obstruction.

Herbert French.

PERSPIRATION, ABNORMALITIES OF.—(See SWEATING, p. 803.)

PHOSPHATURIA. This is an indefinite term: the meaning it conveys to one observer is not always that which it implies to another. Some restrict it to conditions in which the total quantity of phosphates in each day's urine is greater than the average maximum. Others use the term when there is a spontaneous deposit of phosphates in the specimen glass. Others would include cases in which, on applying the boiling-test for albumin, a cloud of phosphates comes down. So loose is the application of the word phosphaturia that it is generally used whenever anything arises to remind the observer ocularly of the fact that the urine contains any phosphates at all.

What is really required is a series of *different* terms to express the following conditions:—

1. Circumstances in which a greater quantity of phosphates is habitually passed in the urine than is the average maximum in health.

2. The spontaneous deposition of phosphates in a urine that has stood in a specimen glass until cold.

3. The spontaneous deposition of phosphates in the bladder, so that the urine is thick and milk-like when it is being passed.

4. The deposition of phosphates as a white cloud when the urine is heated in performing the boiling-test for albuminuria.

Absolute Phosphaturia. The phosphoric acid in the urine is chiefly exogenous, i.e., derived from phosphates in the food. It is chiefly in inorganic combination as salts of the alkalis and alkaline earths. There is a certain small percentage of urinary phosphorus derived from the katabolism of nuclein and lecithin, but the amount derived from these in healthy persons is small as compared with that which comes direct from the food, and phosphates almost disappear from the urine during starvation. There are wide variations in the amounts excreted by normal persons: the average is 3.5 grams per diem, but the healthy limits are as far apart as 1 gram and 8 grams.

It has been asserted that persons whose business entails great wear and tear of the nervous system excrete more than the average amount of phosphates, and the same has generally been held to be true of sufferers from certain nervous disorders of the hysterical or neurasthenic type, particularly when sexual matters are in question. There is very little evidence, however, to show that there is any real increase in the urinary phosphates in these cases. There is often a very abundant deposit of phosphates on applying the heat test to the urine, and this may give the impression that the total quantity of phosphates present must be above the normal: but the impression has not been confirmed by exact analysis. There is only one well-defined condition in which there is absolutely and persistently more phosphate in the urine than healthy limits would allow, and that is *phosphatic diabetes*—a very rare condition, of which the main features are thirst, emaciation, aching in the loins and back, and polyuria without sugar but with an absolute excess of phosphates in the urine.

Physiology of Phosphatic Deposits. The spontaneous deposition of phosphates in urine is nearly always a purely physiological process. A molecule of phosphoric acid, H_3PO_4 , contains three hydrogen atoms. Each of these can be replaced separately by an atom of any monobasic metal, such as sodium. Three types of salts are formed, according as one, two, or three of the hydrogen atoms have been replaced, as in the following examples:

NaH_2PO_4	-	-	Sodium dihydric phosphate
Na_2HPO_4	-	-	Sodium monohydric phosphate
Na_3PO_4	-	-	Sodium phosphate.

These salts may all be present in the same urine, the proportions of each varying with the amount of phosphoric acid present, on the one hand, and the total amount of bases (i.e., sodium, potassium, calcium, etc.) and the total quantities of other acids present in the form of chlorides, sulphates, and so forth, on the other. The greater the quantity of chlorides and sulphates the greater will be the amount of the metallic bases required to form them, and consequently the less will be the amount of bases left to combine with phosphoric acid: the result must then be a relative excess of NaH_2PO_4 . Conversely, the scantier the chlorides and sulphates, and the more abundant the bases, the greater will be the proportion of Na_2HPO_4 and Na_3PO_4 .

Now the three sodium salts differ from one another in at least two physical respects—their action upon litmus, and their solubility in water. Sodium dihydrogen phosphate (NaH_2PO_4) turns blue litmus red—in other words, it is an acid phosphate. The acidity of ordinary urine is mainly due to it. Sodium monohydrogen phosphate (Na_2HPO_4) is also an acid salt technically speaking, and there are some colour tests which exhibit the acid reaction with it: litmus, however, is not one of these, for NaH_2PO_4 turns red litmus blue. When a given urine contains more Na_2HPO_4 than NaH_2PO_4 , the reaction of that urine to litmus is alkaline: that is to say, it turns red litmus blue and does not turn blue litmus red. Some urines have what is known as an amphoteric reaction—they turn red litmus bluish and blue litmus reddish—a different thing from neutrality of reaction, in which neither red litmus nor blue is turned in colour at all. The cause of the amphoteric reaction of a urine is the even balance in that urine of the Na_2HPO_4 on the one hand and of the NaH_2PO_4 on the other.

Now the dihydrogen phosphate is much more soluble in water than is the monohydrogen phosphate, whilst the tribasic phosphates are as a rule far less soluble still. When it is stated, therefore, that phosphates are more soluble in acids than they are in alkalis, it must be remembered that it is not a question of a difference of solubilities of the *same* salt of phosphoric acid, but of an acid urine containing the bulk of its phosphates in a salt *different* from the one present in an alkaline urine. The very fact of a urine being alkaline means that there is relatively little of the more soluble NaH_2PO_4 present, and relatively much of the less soluble Na_2HPO_4 and Na_3PO_4 . Conversely, the fact that a urine is acid implies that the phosphates are relatively more abundant in the soluble NaH_2PO_4 form than they are either as Na_2HPO_4 or Na_3PO_4 . As a matter of fact, the three degrees of phosphates of sodium, potassium, and ammonium are all so soluble that they practically never become precipitated spontaneously, nor do they take part in forming calculi. It is the phosphates of calcium and magnesium that form precipitates, but what has been said above of sodium phosphate applies equally to calcium and magnesium phosphates. The less acid a urine is, the more will the less soluble varieties of calcium and magnesium phosphate preponderate, and it is on this account that phosphates come down in alkaline or neutral rather than in acid urines.

Again, it is often stated that phosphates are less soluble in hot urine than they are in cold, and this is given as the reason for the cloud of precipitated phosphates that so often forms when a urine that is not already very acid is boiled. This, however, does not express the real reason for the cloud: the heat does not precipitate the same phosphate as the cold urine contained, but leads to the formation of a different, and less soluble, phosphate. The calcium monohydrogen phosphate dissociates into calcium dihydrogen phosphate and normal calcium phosphate: it is the latter which is so insoluble that it comes down:

4CaHPO_4	$\text{Ca}_3(\text{PO}_4)_2$	$\text{Ca}(\text{H}_2\text{PO}_4)_2$
Medium solubility	Relatively insoluble, and so coming down as a cloud	Relatively the most soluble of the three

Milky Urine. The urine of many healthy people, especially children, and eaters of large public dinners, is sometimes milk-like when it is passed soon after a full meal. Many

a person has become alarmed at the sight, and has feared some grave disorder of the sexual organs or functions, especially either gonorrhoea or spermatorrhoea. The condition is physiological. It results from increased quantities of hydrochloric acid being required in the stomach at the time. The result of this is that the urine temporarily contains such an abundance of bases in proportion to acids that the less soluble monohydrogen phosphates exceed the more soluble dihydrogen phosphates, and they may become precipitated even in the urine that is still in the bladder. The commonest salt to come down is calcium monohydrogen phosphate, CaHPO_4 , which is either amorphous, or else assumes the form familiar as 'stellar phosphate' (Fig. 498). MgHPO_4 may come down with it in the form of amorphous particles, or as needles.

Fig. 498. — Stellar phosphate crystals (calcium phosphate).

The alternation between oxaluria and phosphaturia exhibited by some individuals is discussed on p. 523.

Ammonio-magnesium Phosphate. — This, generally known as triple phosphate, MgNH_4PO_4 , is comparatively insoluble, and when precipitated it nearly always assumes the form of prisms the familiar 'knife-rest' or 'coffin-lid' crystals (Fig. 499). It is clear that these will come down only when the urine contains ammonia. The latter may of course have been produced by ammoniacal decomposition of urea after the urine was passed. If urinary decomposition after passage can be excluded, however, it is usually stated that the presence of ammonio-magnesium phosphate crystals indicates a purulent lesion in the urinary tracts, especially in the bladder. It is quite true that ammoniacal urines from cases of cystitis often abound in crystals of triple phosphate. The diagnosis is given by the pus cells and

Fig. 499. Triple phosphate crystals.

so forth, however, and not by the triple phosphate crystals. It is important to remember, moreover, that each day's urine normally contains enough ammonia for ammonio-magnesian phosphate crystals to occur in an absolutely healthy urine, even apart from decomposition on standing. This fact detracts very greatly from the value formerly attributed to the detection of triple phosphate crystals in the urine. Indeed, the importance of phosphates in the urine lies almost entirely in the fact that errors of interpretation may arise unless their physiological behaviour is understood. The chief chemical test is the addition of dilute acetic acid, which causes a precipitate of phosphates to clear up. The main importance of recognizing them correctly is to avoid mistaking phosphates for pus in the case of a spontaneous deposit, for spermatozoa, or gonorrhoea, when the urine comes milky from the urethra, or for albumin in the case of the boiling-test for the latter.

Herbert French.

PHOTOPHOBIA, or intolerance of light, may be due to three main groups of causes, namely :

1. Causes in the Eye itself:—

Foreign body	Iritis	Eye-strain from close work in
Injury	Cyclitis	those suffering from uncorrected
Conjunctivitis	Glaucoma	errors of refraction,
Ophthalmia	Retinitis	especially astigmatism and
Keratitis	Retrobulbar neuritis	hypermetropia
Ulceration of the cornea		Albinism.

2. Certain Occupations:

Involving work under eye-straining conditions, such as affect furnace stokers, electric steel welders, workers in strong sunlight, those who are exposed to the dazzle of snow in strong sunshine, those who come out into strong daylight after prolonged work in the dark as in coal-pits, those who work much with X rays. Some persons are unable to stand any strong light, whether of the sun, gas, or electric.

3. Causes not primarily in the Eye itself :

a. Some fevers, especially :

Measles	Influenza	Typhus	Malaria.
---------	-----------	--------	----------

b. Intracranial lesions :

Tuberculous meningitis	Epidemic cerebrospinal meningitis	Syphilitic pachymeningitis
Suppurative meningitis	Acute encephalitis	Cerebral tumour
		Cerebral abscess.

c. After the administration of some drugs :

Arsenic	Potassium iodide	Potassium bromide.
Quinine		

d. Functional conditions :

Migraine	Tic douloureux	Hysteria	Sick headache.
----------	----------------	----------	----------------

e. Supra-orbital herpes zoster.

f. Severe anaemia (see ANÆMIA, p. 25).

g. Secondary to dyspepsia or constipation.

h. Malingering.

Some idea of the cause will generally present itself as soon as the patient gives an account of how the trouble began and how it has progressed. By itself photophobia is seldom a symptom of diagnostic significance, and nearly always there will be other symptoms to assist one. The eyes should be examined carefully to find or exclude a local cause, especially iritis or glaucoma, which are the most serious of the local lesions associated not only with severe photophobia, but also with acute pain in the eye (see EYE, ACUTE INFLAMMATION OF, p. 285). Retinal changes will be discovered by ophthalmoscopic examination (see OPHTHALMOSCOPIC APPEARANCES, p. 517). *Retrobulbar neuritis* may not cause any visible change in the optic disc, at any rate not until several days have elapsed, by which time optic neuritis may be visible ; but it may be suggested by the rapid onset of impaired vision without increased intra-ocular tension as in glaucoma, going on perhaps to temporary complete blindness (p. 923).

Eye-strain resulting from errors of refraction requires special ophthalmic knowledge for its exact determination, though it may be suggested by the circumstances of the case.

Occupation photophobia will be likely if the patient works under peculiar conditions of light, though it will be necessary to exclude organic lesions in the eyes by a thorough ophthalmic examination. When local eye conditions have been excluded definitely, the cause of photophobia will generally be either pretty clear at once or soon, or else open to so much doubt that the actual cause may be one of conjecture only.

It will not be the photophobia, but other symptoms, such as the rash, the fever, and the course of the disease, which will give the diagnosis in cases of *measles*, *influenza*, or *typhus fever*; headache, vomiting, optic neuritis, and the results of lumbar puncture or the Wassermann test in the case of *meningitis*, *encephalitis*, *cerebral tumour*, or *syphilitic pachymeningitis*; knowledge of the drug given and cessation of the photophobia when it is stopped in the case of *arsenic*, *potassium iodide* or *bromide*, or *quinine*.

Migraine and *tic douloureux* are so characteristic in their attacks that they are both diagnosable as a rule from the patient's story: photophobia may be severe in either, or even extreme in *tic douloureux*, in which, during the excruciating paroxysms of facial pain, the patient will often desire to remain for days in an absolutely darkened room: exposure to any light may bring on a paroxysm.

Supra-orbital herpes is generally obvious from the eruption of groups of vesicles on a reddened base along the course of one supra-orbital nerve: and the photophobia is generally unilateral: it may persist, however, for weeks or months after the eruption has subsided, and then its origin may be overlooked.

Malingering can be diagnosed only by catching the patient unawares and discovering that when he is not watched he is able to read in an ordinary light notwithstanding the photophobia he complains of. *Dyspepsia*, *constipation*, and *severe anemia* are somewhat problematical as causes of photophobia, but might be regarded as its origin in a patient who, suffering from any of the three, also had photophobia without any other discoverable cause, especially if the photophobia disappears when the patient is cured of the constipation, the dyspepsia, or the anemia, respectively.

Sick headache is a periodic malady of many women and some men. Headache of great severity is the chief symptom, lasting a whole day or even longer: gastric functions are in abeyance during the attack, so that food in the stomach remains undigested and medicines unabsorbed: the patient may feel ill enough to have to stay in bed: towards the end of the attack vomiting occurs once or several times, and by the next day the patient feels perfectly well again. Dislike of any but a dim light is common during the attack. The diagnosis is generally based upon the patient's familiarity with similar symptoms on many previous occasions. The malady is often hereditary: possibly it is related to migraine.

Biliousness is a very common ailment, due to many different causes, especially injudicious eating or drinking, or to deficient fresh air or exercise. Some cases of recurrent biliousness are closely allied to sick headache and to migraine. During an attack the tongue is coated and the bowels are inactive. The precise pathology of the condition is little understood, but the diagnosis is not difficult, although it is important to make a routine examination to exclude more serious lesions. Photophobia, though common in a minor degree in bilious attacks, is seldom very marked.

Hysterical photophobia is met with only occasionally, but when it occurs it may be extreme: that is to say, the patient may mimic—not intentionally, as in the case of a malingerer, but without at all wishing to do so—so extreme a degree of intolerance to light that she may cover her eyes with deep-tinted glasses, or even cover her whole head with an impervious dark robe: and may perhaps require to be led about when she walks, like a person totally blind. It is this over-doing of the part that may give the clue to the diagnosis. Naturally a thorough examination, particularly of the eyes, will be required to exclude organic disease, but if functional photophobia appears to be the diagnosis in a particular case the suspicion may be confirmed by the way the symptom can be made to disappear by sufficiently bold suggestion.

Herbert French.

PIGMENTATION IN THE MOUTH generally consists of flecks, streaks, or spots of pale brown or pale sepia discoloration of the mucosa, especially upon the inner aspect of the cheeks along a line roughly corresponding to the level of the closed teeth ; with or

Figs. 500, 501. Pigmentation of the buccal mucosa and tongue in Addison's disease.

without similar pigment spots, streaks, or patches upon the mucous surface of the lips, seen best when the latter are everted in a good light ; upon the roof of the mouth, generally upon the soft palate or upon the posterior part of the hard palate rather than more anteriorly ; upon the gums occasionally ; and sometimes upon the sides of the tongue. Such pigmentation of the buccal mucosa immediately suggests *Addison's disease* (*Figs. 500-502*), especially if there is generalized pigmentation of the skin at the same time, extreme asthenia, a low blood-pressure, a tendency to vomiting or to fainting attacks on any exertion, with inability to maintain any effort, mental or physical. Unfortunately, however, although such buccal pigmentation is highly suggestive of Addison's disease, it is not pathognomonic, for it has been noted in a variety of other conditions also.

Thus, it is an almost constant feature in persons who have *negro blood* in their ancestry, even though this be from one great-grandparent only. This source of difficulty in interpretation is commoner, perhaps, in Africa, the West Indies, and America, than it is in Britain, but even here it makes it uncertain sometimes whether one is to diagnose Addison's disease or not.

Then in *pernicious anaemia* buccal pigmentation precisely similar to that of Addison's disease is met with occasionally (see *Fig. 64*, p. 45), and unless the blood-count is very definite (p. 30) it may be difficult, even up to the time of post-mortem examination, to say which of the two conditions the patient is suffering from. Probably the right course to follow then would be to treat the case with arsenic or by blood-transfusion and watch the effect ; pernicious anaemia rallies, temporarily, to these remedies much more certainly than Addison's disease does.

Fig. 502. Pigmentation inside the cheek and on the lip in Addison's disease.

Arsenic itself may cause pigmentation, not only of the skin, but also within the mouth, as was shown by some of the cases in the Manchester epidemic of arsenic in beer poisoning. Some have supposed that the buccal pigment in pernicious anaemia is due to the arsenic employed in treatment: that this is not so, however, is shown by the fact that some cases of pernicious anaemia exhibit pigmented spots inside the mouth even before any arsenic has been given: the patient from whom *Fig. 64* was taken was an instance in point.

One has also seen pigmentation of the buccal mucosa, suggesting Addison's disease, in *chronic cachectic conditions* in which the suprarenal capsules have seemed macroscopically healthy at autopsy. In a case of *phthisis*, for example, so pigmented was the mouth that it seemed reasonable to diagnose that the tuberculous process was affecting the suprarenals as well as the lungs: yet after death the suprarenals were normal, and one can only suppose that the buccal pigment resulted from the phthical cachexia which had caused a general tendency to pigmentary degeneration everywhere. In another case Addison's disease was diagnosed during life for the same reason, but at autopsy a *carcinoma* of the splenic flexure of the colon was found, with secondary deposits in the liver: there had been asthenia and general cachexia, and apparently it was the latter which was responsible for the pigment changes. In a third case the patient was both anaemic and cachectic, without any other definite symptoms, and there was extensive pigmentation in the mouth. The blood-count showed extreme anaemia, with a colour index that was approximately 1. The doubts during life lay between Addison's disease and pernicious anaemia: both suggestions proved wrong, for at autopsy syphilitic gummata of the liver were found, together with *tertiary syphilitic amyloid disease*, but without any decided abnormality in the adrenals.

Fortunately, buccal pigmentation from cachectic states such as phthisis, cancer, and syphilis is rare, though the possibilities have to be kept in mind. In the great majority of cases, if pernicious anaemia, arsenic, and negro blood can be excluded, Addison's disease will be diagnosed correctly if the patient is clearly asthenic and ill without any very definite physical signs, but with marked pigmentation within the mouth. *Herbert French.*

PIGMENTATION OF THE

SKIN. Anomalies of the natural pigmentation of the skin, on the side either of excess or deficiency, may be due to irritation of the abdominal sympathetic, and particularly the solar plexus, leading to *general* pigmentation, or to the exudation or extravasation of the colouring matter of the blood, producing *local* pigmentation. Local

pigmentation may be brought about by the action of irritants, may result from a condition of hyperaemia, or may be a sequela of skin eruptions. It may be caused by counter-irritants such as vesicants, hypodermic injections (*Fig. 503*), or some other form of external irritation, especially scratching, as in vagabond's disease *phthiriasis*; but in some cases it is impossible to trace the cause. Chloasma is a sequela or an accompaniment of cutaneous eruptions, or is the result of abnormal conditions of the uterus or of other abdominal viscera, or of cachexia. It is most often met with as *chloasma uterinum*, which may occur not only in connection with pregnancy but also in association

Fig. 503. Taches bleues: blue-black pigment spots in the skin due to hypodermic injections of omuquin. Precisely similar pigmentation may result from injection of morphia or of heroin.

with any form of uterine irritation. The smooth yellowish-brown patches are seen most commonly on the forehead, but almost the entire face may be involved, and also the trunk and limbs. Somewhat similar irregularities of pigmentation occur in *rheumatoid arthritis*, *pernicious anaemia*, *Hodgkin's disease*, *Graves' disease* (*Fig. 504*), *abdominal tuberculosis*, *constipation*, *chronic intestinal stasis*, and other disorders of the abdominal viscera, and in cases in which *arsenic* has been given over long periods (*Fig. 505*). In *Addison's disease* there is a general bronzing of the skin (*Fig. 506*), together with pigment deposits

Fig. 504.—A case of typical exophthalmic goitre, to illustrate general pigmentation of the skin in this disease.

in the mucous membranes of the mouth (*Figs. 500–502*), anus, vulva, and urethra; buccal pigment, however, does not by itself prove that Addison's disease is present, for precisely similar pigmentation in the mouth is observed in some cases of pernicious anaemia (*Fig. 64*, p. 45), of phthisis without suprarenal disease, and of malignant disease; whilst negro blood in the ancestry often causes buccal pigmentation in perfectly healthy persons.

Pigmentary abnormalities of the skin occur also in *cachexia* associated with

Fig. 505.—Pigmentation due to arsenic given medicinally in a case of lymphadenoma.

malaria, cancer, nodular leprosy, and secondary syphilis: in malaria, a yellowish-brown to black; in cancer, a sallow tint; in nodular leprosy, a fawn colour early in the disease,

Fig. 506. Extreme pigmentation of the skin in a case of Addison's disease: islands of normal skin contrast with the generalized pigmentation of the rest. The normal man on the left serves to accentuate the darkness of the patient.

and a general bronzing at a later stage; in secondary syphilis, an earthy tint affecting the face. In the rare condition known as *ochronosis*, the skin, cartilages, and sclerotics are blackened, as the result in some cases of alkaptonuria, in others of the prolonged absorption of carbolio acid. In *harmochromatosis*, another rare condition, apparently due to diseases of the alimentary tract and liver, the patient may be pigmented from head to foot, the prevailing colour being a deep blue-grey slate tint. The diagnosis of *urticaria pigmentosa seu nigricans* is generally clear. Pigmentary deposits in the skin form only part of the skin changes characteristic of *Kaposi's disease*. The pigmentation seen

in *bronzed diabetes* can scarcely be misinterpreted if, when the urine is examined, glycosuria be found: most cases of this form of diabetes have cirrhosis of the liver as well, and there is a history of alcoholism.

Fig. 507. Extensive syphilitic leucomelanoderma.

Fig. 508.—The same case as Fig. 507, seen from behind.

The diagnosis of the various forms of pigmentation is usually easy, though the particular cause can only be deduced from the general symptoms. Chloasma can be differentiated from *chromidrosis*, by observing that in the latter condition the colour, which is derived from the exuded secretions, disappears if washed with ether or chloroform. In *tinea versicolor*, and some other fungous diseases which resemble chloasma, the patches are not smooth but scaly, and the discoloration can be scraped off. The *pigmentary syphilide*, which may take the form of a diffused brownish hue, brownish spots, or dappled patches, is seldom met with except on the neck, but sometimes it may take the form of widespread leucomelanoderma (Figs. 507 and 508). Question may arise between chloasma and *leucodermia* (vitiligo) when in the latter condition the white areas have spread over the greater part of the body, and are taken for the normal colour: but in leucodermia the border of the pigmented area is concave, whereas in chloasma it is convex. Moreover, in leucodermia the history is that of the formation of white patches, surrounded by a pigmented border, which may spread until large areas, and even the whole surface of the body, are affected.

Leucodermia has in its turn to be distinguished from sclerodermia, morphea, macular leprosy, pigmentary syphilide, and partial albinism. The skin is not stiff and thickened as it is in *sclerodermia*. The edges are not streaked with small dilated vessels, making a pink or violet border, as in *morphea* (Fig. 509), nor is there any intermingling of atrophic striae. The patches are not destitute of sensation as in *nerve leprosy*, nor, though it has been styled 'white leprosy', has leucodermia any other resemblance to that affection save the colour of the patches. Doubt as between leucodermia and a congenital condition like *partial albinism* could only arise by disregarding the history. Of albinism itself, whether partial or universal, nothing more need be said here: for though it is an abnormality of pigmentation, its true character can never be in question. Nor need jaundice be mentioned, for that condition forms the subject of a separate article.

Discoloration of the skin may be due to the prolonged administration of drugs. Thus picric acid or employment in connection with T.N.T. may turn the skin and the conjunctivae yellow: arsenic may cause a peculiar greyish, brownish, or freckle-like pigmentation (Fig. 505, p. 643); nitrate of silver may set up the condition known as *argyria*, in which the integument and the mucous membrane, particularly in situations exposed to light, take on a bluish-grey or greyish-black colour, especially on the face and the flexor aspects of the limbs. This condition may closely resemble haemochromatosis and similar abnormalities, but the history of protracted use of the drug will make the diagnosis clear. Since, however, arsenic may be derived from some unsuspected source, as was the case in the peripheral neuritis epidemic in and around Manchester due to beer containing it as an impurity, chemical analysis of the hair should be made, for arsenic becomes stored up in the hair that grows whilst this is being taken.

An extreme degree of deep purplish plum-coloured discoloration of the entire skin may result from long-continued *dermatitis exfoliativa* (Fig. 510), but the severe dermatitis has generally given the clue to the diagnosis long before the pigmentation becomes extreme. *Acanthosis nigricans* (Fig. 257, p. 295) is a rare but characteristic state of affairs in which the patient seems at first sight to have smeared the skin of neck

Fig. 509. Morphea of the back. The condition was one of many years' duration. Note the borders of the morphea patches, the darkened edges during life exhibited small dilated vessels with a dull violet hue. (Photograph kindly lent by Dr. John Simons, Penzance.)

or trunk with coal dust, the causal lesion being in nearly all such cases carcinoma of the stomach. *Pellagra* (Fig. 224, p. 280) is another rarity in which pigmentation of the backs of the hands and forearms and of the face may be a prominent feature; it is described on page 279.

Fig. 510.—Chronic dermatitis exfoliativa. From a sketch of a case, to illustrate the plum-coloured pigmentation of the skin that may occur with this disease.

Ernest Dore.

PILIMICTION signifies the passage of hairs in the urine: it is a rare symptom, but when it does occur it almost invariably signifies that the patient has a pelvic dermoid cyst which has become inflamed, thereafter opening into the bladder and discharging its contents via the urinary passages. The condition has been observed in men, but it is less uncommon in women. Subacute or acute cystitis accompanies the event, with vesical pain, frequency of micturition, and pyuria. The only difficulty likely to arise in diagnosis is when the patient avers that she has passed hairs with her urine when in reality the hairs produced have merely fallen into the chamber without having been passed per urethram.

Herbert French.

PLANTAR REFLEX, EXTENSOR.—(See BABINSKI'S SIGN, p. 87.)

PLEURAL EFFUSION.—(See CHEST, p. 132 et seq.)

PNEUMATURIA—or the passage of gas per urethram, either along with or independently of urine—is a rare symptom, but when it does occur it is very striking, particularly in males.

It may be due to one or other of two entirely distinct groups of causes, namely:

1. Communication between the rectum, caecum, vermiform appendix, or other part of the alimentary canal, and the bladder, ureter, or renal pelvis: either directly or via an intermediate gas-containing abscess cavity.

2. Infection of the bladder or other part of the urinary tract by micro-organisms that produce gas, without there necessarily being any breach of surface of the mucosa.

When the cause lies in the first group, the patient is very liable to pass faecal material at the same time as gas, and the differential diagnosis between the various possible lesions is discussed under *FÆCES PASSED PER URETHRAM* (p. 296). It should be added, however, that the passage of gas without faeces per urethram by no means excludes there being a fistulous communication between some part of the alimentary canal and the urinary tract; the fistula may be tortuous, so that gas gets along it, but not faeces. It may happen, moreover, that a lesion such as appendicitis has led to the formation of a local abscess which, owing to its infection by the *B. coli communis*, contains gas; this abscess may open into the bladder and cause the discharge of pus and gas, but no faeces, per urethram. The same applies to other abscesses which, though not arising primarily in connection with the bowel, nevertheless occasionally contain gas from infection by the *B. coli communis*—a suppurating hydatid or ovarian dermoid cyst, for instance, or a pyosalpinx.

Sometimes there may be serious doubts as to whether the gas is finding its way into the urinary passages from some external source, as above, or whether it is being produced *in situ*. In the absence of any rectal or other pelvic or abdominal evidence of disease outside the bladder it will be remembered that certain organisms produce gas when they grow in urine: notably the *B. coli communis*, and in glycosuric cases various yeasts. The urine will be examined for sugar, and if it be present, a catheter specimen will be obtained to see if saccharomycetes are present in the bladder-urine: if so, and if there is no pus or evidence of infection by other micro-organisms, the nature of the pneumaturia will be clear: as a rule in these cases the patient voids urine that is bubbly rather than distinct and separate from the gas. If, on the other hand, no sugar is present, a catheter specimen will be cultivated to find out whether the *B. coli communis* is present, and if so, in what quantity. If it is, and if no sign of any fistulous communication between any part of the bowel, or a gas-containing abscess cavity, and the urinary tracts, can be made out on cystoscopic examination, the presumption will be that the pneumaturia is due to coli bacilluria, although the latter is far commoner without than with pneumaturia. The urine in these cases may contain very little obvious pus and only a trace of albumin; it may be acid, and not foul-smelling or ammoniacal; on the other hand, it may sometimes be so foul and feculent as to cause serious suspicions of a communication between the colon and the bladder even when there is none. A cystoscopic examination will serve to exclude a fistulous opening into the bladder, but it may be much more difficult to exclude a similar communication with the higher parts of the urinary tract, especially the renal pelvis. The latter condition is so rare, however, that it is wiser to diagnose coli bacilluria only unless there is direct evidence of a cause for communication between the bowel and the renal pelvis, such as a carcinoma coli.

Herbert French.

PNEUMOTHORAX, or gas in the pleural cavity, may exist with or without clear fluid, pus, or blood in the lower part of the pleura at the same time. If there is fluid in the cavity along with the air, and the patient's thorax is auscultated whilst it is being actively or passively shaken, a typical succussion splash may be heard, often followed by ringing sounds made by drops of fluid falling from the compressed lung into the pool of fluid beneath. The nature of the fluid—hydro-pneumothorax, pyo-pneumothorax, or hemo-pneumothorax, as the case may be—can seldom be diagnosed except by means of an exploring needle and syringe. Whether associated with fluid or not a complete pneumothorax is generally easy to diagnose on account of the deficiency in movement of the affected side of the chest, the displacement of the heart in the opposite direction, the hyper-resonance to percussion, together with remarkable deficiency or complete absence of the vesicular murmur and voice-sounds. The coin-tap sound, obtained by placing one silver coin on the chest wall, tapping it with another silver coin, and listening through the stethoscope for the ringing echo produced, may serve to confirm the diagnosis, but it is not essential. Partial pneumothorax, in which complete collapse of the lung is prevented by adhesions, is proportionately more difficult to diagnose, but the same type of physical signs, including the coin-tap sound or *bruit d'airain*, will generally be found in these cases, though in less degree than when the pneumothorax is complete. The X rays show an abnormal clearness corresponding to the air in the pleural cavity (Figs. 511-513). It is not sufficient, however, merely to diagnose pneumothorax; its cause has to be determined from amongst the following:

Phthisis: (a) early, (b) late
Rupture of an emphysematous bleb
Gangrene of the lung with necrosis of the pleura
Empyema ruptured through the lung
Instrumental: e.g., after tapping a pleural effusion
Stab or gunshot wound of the chest wall
Epithelioma of the oesophagus ulcerating into the pleura

Gastric ulcer or carcinoma ventriculi, leaking so as to produce a gas-containing subdiaphragmatic abscess, which in its turn may perforate the diaphragm and cause a pneumothorax
Infection of the pleural cavity by gas-producing organisms, such as the *B. coli communis* or the much more virulent organisms of malignant oedema, *B. aerogenes capsulatus* or *B. Welchii*.

The commonest cause by far is *phthisis*: and when the occurrence of the pneumothorax does give rise to symptoms it is generally due to comparatively early phthisis;

indeed, when it comes on acutely with sudden lancinating pain in one side of the chest, associated with rapid shallow breathing, and cyanosis with or without hæmoptysis, in a young apparently healthy adult, it is almost certain that the patient has a tuberculous

Fig. 511. Skiogram of a complete pneumothorax on the right side. Note the airless lung compressed towards its hilum with air outside and above and below it in the pleural cavity; also the flattening of the upper surface of the right cupola of the diaphragm and the displacement of the heart to the left, none of the cardiac shadow lying to the right of the spine.

Fig. 512. Skiogram of an interlobar pyo-pneumothorax. The primary condition was an interlobar empyema which ruptured through a bronchus, as a consequence of which there was recurrent expectoration of foul pus. The diagnosis was indicated by the X-ray findings. Unfortunately the patient sank gradually and died of exhaustion, and the diagnosis was verified at post-mortem examination. It is particularly noteworthy that what appears in the skiogram to be a gross lesion was associated with no departure from normality in the physical signs.

focus at one apex, even though, as frequently happens, there have been no abnormal symptoms previously, such as cough or night sweats, and even though absolutely no abnormal physical signs can be detected at the apex of the other lung. There may be a little sputum, and in this tubercle bacilli may be detected.

Fig. 513. Skiogram of a hydro-pneumothorax. Note the horizontal upper border to the shadow of the fluid.

When pneumothorax is attributed to *rupture of an emphysematous bleb*, there must always remain in the physician's mind a serious doubt as to whether it is not really due to a bleb in the immediate neighbourhood of an undiagnosable tuberculous deposit, and the case should be treated as one of potential phthisis.

If the tuberculous process in the lung has made considerable advance pneumothorax is far less common, because there will almost certainly have been pleurisy with thickening and adhesions sufficient to prevent a complete pneumothorax occurring; nevertheless, in some such cases pneumothorax does develop, and the diagnosis of its cause is easy both on account

of the abnormal physical signs and of the sputum with the tubercle bacilli in it. In a later stage still the occurrence of pneumothorax may cause very little additional

disturbance, on account of the extent of lung already diseased, and although its cause would be obvious enough, the occurrence of the pneumothorax often escapes detection.

When the patient has had a *pleuritic* or *pleural effusion* tapped, detection of air free in the pleural cavity next day is by no means uncommon; it does not follow that this air has leaked in through the tapping instrument, for it is quite as commonly derived from the rupture of superficial alveoli which have been re-expanded rather too rapidly in the withdrawal of fluid by the aspirator. The air generally becomes reabsorbed in a few days, and the temporary pneumothorax is of little significance.

Similar escape of air into the pleural cavity as the result of *cuts, stabs, fractured ribs, or gunshot wounds*, is remarkably rare; this rarity depends upon the fact that the two layers of pleura tend to cohere in a way similar to that which makes two thin sheets of Indian paper difficult to separate, so that when an injury from outside penetrates one layer it nearly always perforates both, and air from within the lung escapes into the subcutaneous tissues instead of into the pleural cavity, and produces surgical emphysema instead of pneumothorax. It rarely happens that an injury separates a sufficient area of the two layers of pleura one from the other to cause a pneumothorax.

All the remaining causes of pneumothorax in the list above are uncommon, and none of them will arise without there having been other symptoms to indicate the nature of the malady. It is possible for an *empyema* to rupture into a bronchus, and so lead to the sudden expectoration of much foul pus, without any pneumothorax arising, or at least none of any extent, because for such an empyema to rupture into the lung it must have been shut off all round by firm pleural adhesions. When pneumothorax results from *gangrene of the lung* due to any cause (p. 322), it is but a terminal factor in an already serious disease, and may even pass without recognition on account of the severity of the symptoms already existing in the case. *Gas-containing abscesses beneath the diaphragm*, such as may either perforate directly into the pleural cavity or lead to infection of that cavity by the *B. coli communis* or other gas-forming organism, never arise suddenly, but are preceded by a simple or malignant ulceration of either the stomach, duodenum, or colon, the symptoms of which will generally have existed for days, weeks, or months; so that if the possibility of gas appearing in the pleural cavity in this way is borne in mind the diagnosis of its origin need not be difficult. The X rays may serve to show a large gas-bubble below the diaphragm as well as gas in the pleural cavity, and that the gas-bubble is not intragastric may be demonstrated by filling the stomach with a bismuth meal and finding that the gas-bubble does not become blackened.

Fig. 514. Skiagraph, taken after a bismuth meal, to illustrate herniation of the stomach into the chest. (Cf. Dr. R. L. Roberts.)

Pneumothorax due to gas production by *gas gangrene* organisms is preceded by a history of chest injury or gunshot wound; as a rule the first effect of the latter is a hemothorax, gas gangrene organisms develop in the blood-clot, and the pneumothorax becomes apparent after an interval of two or more days; the patient begins to look much more toxic than seems warrantable on general grounds, the temperature and pulse-rate rise markedly, and when the chest is needled gas of a peculiar sweet smell escapes; the fouler the smell the less likely is the condition to be due to gas gangrene infection; the sweeter the smell the more urgent the need for surgical drainage.

One rare condition that may be mistaken for pneumothorax is *herniation of the stomach* into the chest through a hole in the diaphragm; the hole may be congenital, but more often it is due to injury, for instance by gunshot wound; the fact of herniation of the stomach may be established by skiagraphy after a bismuth meal (Fig. 514).

Herbert French.

POLYCYTHÆMIA is the term used to denote a material increase of the red corpuscles above their normal number per cubic millimetre of blood. In males they should average 5,000,000 per c.mm.; in females, 4,500,000. Any considerable increase above these figures, for instance up to 6,000,000 per c.mm., or more, constitutes polycythæmia; though it is noteworthy that recent hæmocytometers seem to be of different calibre from those of former years, many giving 6,000,000 red cells per c.mm. in patients whose count would formerly have been 5,000,000. Whereas 5,000,000 was regarded as the normal maximum years ago, there is a tendency, with modern instruments, to find 6,000,000 in normal people nowadays—purely an instrumental change, one supposes. Figures as high even as 14,000,000 are reached sometimes, however, in polycythæmic states. The following are some of the conditions in which polycythæmia occurs:—

1. Congenital heart disease of the type spoken of as *morbus cæruleus*—generally due to pulmonary stenosis (see *Fig.* 126, p. 143, and *Fig.* 166, p. 196).

2. Persons who live in high altitudes.

3. Patients afflicted with chronic shortness of breath, with a tendency to periodic cyanosis, particularly cases of (*a*) mitral stenosis, (*b*) fibroid lung with and without bronchiectasis, (*c*) chronic bronchitis and emphysema, (*d*) spasmodic asthma, (*e*) some renal cases.

4. Patients who have recently lost a quantity of fluid from the tissues, the result of such conditions as (*a*) severe vomiting, e.g., the uncontrollable vomiting of pregnancy; (*b*) severe diarrhœa, e.g., the summer diarrhœa of infants, cholera, ptomaine poisoning, arsenic; (*c*) inability to obtain fluid to drink, especially if there exists already a disease tending to polyuria, such as diabetes mellitus, diabetes insipidus, or granular kidney.

5. From the prolonged use of certain drugs, especially acetanilide, veronal, and some others of the type that may cause methæmoglobinuria (p. 357); cantharides.

6. Splenomegalic polycythæmia (Osler's disease, Vaquez' disease, erythræmia).

As a rule the diagnosis of the cause of polycythæmia in a given case is not difficult. When it is due to *congenital heart disease* it is nearly always associated with an extreme degree of cyanosis without proportionate dyspnœa, and with clubbing of the fingers, both these dating from birth or early childhood. The patient is generally young, though some survive into adult life. There is not always a cardiac bruit, and the precise lesion will then be obscure; often, however, percussion shows increased cardiac dullness to the right of the sternum, and upwards towards the second left rib, indicating increased size of the right auricle and ventricle; and in most cases there is either a loud rumbling or blattering systolic bruit of pulmonary stenosis, heard loudest in the second left space close to the sternum, but also audible over the greater part of the precordial region, and often over both sides of the chest in front and behind; or else a very similar universal systolic bruit, differing chiefly in having its maximum intensity either behind the sternum between the two fourth ribs, or else in the fourth left intercostal spaces close to the sternum, indicative of patent septum ventriculorum. These two lesions may both be present in the same patient, and they are the commonest cause in cases of *morbus cæruleus* that survive infancy. The red corpuscles seldom number less than 6,000,000 per c.mm., and in some cases they have been no fewer than 14,000,000 per c.mm. The percentage of hæmoglobin is also increased greatly, but usually to a less degree than are the red cells, so that the colour index falls below 1. This applies to nearly all causes of polycythæmia. There is no simultaneous increase in the number of leucocytes per c.mm., and the differential leucocyte count falls within the normal limits. It is noteworthy that cases of persistent ductus arteriosus seldom present either cyanosis, clubbed fingers, or polycythæmia.

Residence at *high altitudes* often causes polycythæmia. The increase is seldom extreme, but the red cells not infrequently reach 7,000,000 or more per c.mm. This rule is not by any means universal, however, though upon the whole the higher the altitude the higher the normal average number of red cells per c.mm., particularly in those who have resided long and continuously in the mountains. The individuals are not ill; it is merely that their red cells stand at a higher figure normally than do those of dwellers nearer sea level.

Quite apart from the presence or absence of anasarca, patients suffering from chronic lesions which tend to produce dyspnœa are apt to have polycythæmia, particularly when the lesion causes marked redness of the lips. This is well seen in many cases of *mitral*

stenosis. There is no similar polycythemia in aortic cases unless mitral disease is present as well, and the red cells are much less increased in mitral regurgitation than in mitral stenosis. In the latter they often reach 6,000,000 or even 7,000,000 per c.mm., and it would seem to be an attempt on nature's part to try to compensate for the failing circulation by distributing the hæmoglobin over a larger corpuscular area. The same explanation probably accounts for the similar polycythemia due to morbus ceruleus, and to high altitudes, and to certain cases of *fibroid lung*, *bronchiectasis*, *emphysema*, *chronic bronchitis*, *renal disease* with chronic dyspnoea, and *spasmodic asthma*, in which some degree of polycythemia, though not the rule, is sometimes met with, just as it is in mitral stenosis. The colour index is less than 1, for although the hæmoglobin is increased, it is less so than are the red cells. The leucocytes remain unaltered. The polycythemia will seldom if ever be the most prominent symptom in the case, so that the diagnosis will nearly always have been made upon other grounds—the presystolic bruit at the impulse; the displacement of the heart towards that side where the lung presents an impaired note, with or without crackling râles and bronchial breathing; and so on. The maintenance of the polycythemia is important, however, and therapeutic measures should be directed to this end, for many cases of mitral stenosis with 5,000,000 red cells per c.mm. are relatively anæmic; they should have 6,000,000 or more.

The effect of *cholera*, *ptomaine poisoning*, *arsenic*, *summer diarrhœa* of infants, *severe thirst* that cannot be assuaged, the *toxæmia of pregnancy*, in concentrating the blood by withdrawing or withholding fluid from it, and thus producing some degree of polycythemia, is an acute condition which is to be counteracted by continuous saline infusion or some similar method of restoring fluid to the tissues. The polycythemia seldom reaches any marked degree except in quite early stages, for instance in cholera; later, the red cells disintegrate more rapidly than they are replaced. In measuring the concentration of the blood in these conditions it is of less value to count the red cells than to measure the specific gravity. This is done most readily by the chloroform and benzene method. The specific gravity of chloroform is high, that of benzene is low, and by mixing the two in different proportions it is possible to obtain fluids of every intermediate specific gravity. A mixture of the two of the normal specific gravity of the blood, viz., 1056, is made, and poured into a specimen glass of sufficient depth to allow a urinometer to float in it. For strict accuracy, certain corrections in the readings of the ordinary urinometer are required, but for emergency use the instrument will serve. The lobule of the patient's ear is pricked, a large drop of blood is allowed to fall into a suitable small cup or other receiver containing some of the chloroform-benzene mixture, and thence transferred to the main bulk of the fluid in the specimen glass. If the blood-drop sinks, more chloroform must be added; if it floats, more benzene; ultimately a point is reached at which the blood-drop neither sinks nor floats; the specific gravity of the chloroform-benzene mixture is then the same as that of the blood. In cases of collapse from loss of fluid there is a rise in the specific gravity of the blood even when there is no polycythemia—and the greater the rise, the greater the need for infusion.

The effects of *drugs* in producing polycythemia will be suggested if the patient exhibits the lavender-bluish tint of lips and nails characteristic of methæmoglobinæmia (*Fig. 167*, p. 197), and inquiry as to the drugs that are being taken will perhaps confirm the diagnosis. Certain patients exhibit a special proclivity to methæmoglobinæmia and polycythemia from acetanilide. Cantharides is a less common cause because the drug is seldom used; in certain cases of poisoning by Spanish fly, however, the red corpuscles have been noted to rise from 5,000,000 to 10,000,000 per c.mm. by the third day, with a leucocytosis up to 24,000, the red corpuscles returning to normal numbers again in a week or ten days if the patient survives.

Splenomegalic polycythæmia is a somewhat rare condition, that is also termed *Osler's disease*, *Vaquez' disease*, *polycythæmia vera*, *erythræmia*, or *erythrocythæmia*. Its name suggests its main features, which are: Enlargement of the spleen, increase in the red cells up to as many as 10,000,000 per c.mm., or even more, and duskiess or lividity of the face (*Fig. 515*) and of the extremities. The nature of the malady is still obscure, though some regard it as due to disease of the bone-marrow. It affects adults and females rather than children and males, and its course is chronic. It only remains to add that whereas to be typical the spleen must be enlarged, there are cases, probably of the same

affection, in which, without the spleen becoming palpable, the only definite clinical signs are progressive lividity and polycythæmia.

Occasionally one meets with polycythæmia in conditions in which, theoretically, it ought not to be present. For instance, in *lymphatic leukaemia*: in association with an enlarged spleen and enlarged lymphatic glands there may be 200,000 leucocytes per c.mm. with a large preponderance of lymphocytes in the differential leucocyte count; in most such cases the red cells are diminished, but sometimes, in association with what would

FIG. 515. The characteristic facies of splenomegalic polycythæmia.

otherwise be typical lymphatic leukaemia, the red cells may number 7,000,000 per c.mm. The precise nature of such cases is not known: they are unnamed, but clinically they are, as it were, a combination of lymphatic leukaemia and of splenomegalic polycythæmia in the same individual. The prognosis is better than if they presented the characters of leukaemia only.

Herbert French.

POLYDIPSIA.—(See THIRST, EXTREME, p. 874.)

POLYURIA.—The term polyuria signifies the passage of more than the average amount of urine per diem. It may be either (I) *Transient*, or (II) *Continued*. It is important not to mistake frequency of micturition for polyuria, for although the latter almost necessarily causes the former, there are many conditions that lead to frequency of micturition without polyuria—for example, tuberculous ulceration of the bladder, enlargement of the prostate, or urethral stenosis, in all of which urine may be passed frequently, but in small quantities at a time. In case of doubt the total amount of urine passed in each period of twenty-four hours should be measured. The normal limits are very wide, the

average being about 50 ounces per diem, more being passed in cold weather than in warm, during rest than after exercise, waking than sleeping, and after drinking than after taking little fluid by the mouth. The point at which polyuria begins is arbitrary; if a patient passes 70 ounces or more per diem it is almost certain to attract attention, and therefore to merit the term polyuria. In degree, the polyuria due to causes in Group I seldom exceeds 100 ounces a day; some of the causes in Group II, especially diabetes mellitus and diabetes insipidus, may cause polyuria to the extent of 200 ounces, or even 300, 400, 500, or more, per diem.

In arriving at the differential diagnosis of the cause in any given case one of the first points to note is whether the polyuria is persistent, or whether, even if recurrent, it is transient. Any of the causes that usually give persistent polyuria may in some individuals produce the symptom intermittently, but upon the whole one may classify the causes of polyuria as follows:

I. CAUSES OF TRANSIENT POLYURIA.

1. After drinking abundance of water or other fluid.
2. After drinking fluids containing diuretic principles, such as alcohol (wine, malt liquors, spirits); caffeine (tea, cocoa, coffee); citrates or tartrates (artificial lemonades).
3. As the result of nervousness, or of nervous attacks, such as:—

Medical examination for life assurance	After an epileptic attack
Preparation for some physical or mental competition	After migraine
Hysteria, especially during recovery from an acute outburst	After an asthmatic attack
Neurasthenia	After an attack of angina pectoris
	Periodic polyuria, apparently without cause.

4. Hydronephrosis, with periodic emptying of the renal sac.
5. The cold stage of a malarial attack.
6. In some cases of convalescence from a febrile illness, such as enterica.
7. As the result of the clearing up of extreme oedema or serous effusions—for instance, during recovery from acute nephritis; mitral stenosis, with heart failure; cirrhosis of the liver; and so on; especially if the fluid clears up quickly after giving diuretic remedies, such as blue pill, digitalis, calomel, copaiba resin, potassium salts, diuretin, sodium-theocin-acetate, uva ursi, broom tops, or dwarf elder.

When the cause lies in Group I its nature is generally obvious, though it is essential to examine the urine carefully for sugar, albumin, and renal tube-casts, for purposes of exclusion. Nevertheless, the diagnosis may be in doubt until the course of the symptom has been watched for a while. For instance, polyuria may seem to be due to profuse drinking, when really the kidneys are granular and contracted; or in a life insurance case, nervousness may seem to be the cause, when there has really been a bout of drinking; or, again, the drinking may be secondary to the extreme thirst produced by diabetes insipidus.

Excessive Drinking. When due to drinking water, tea, wine, spirits, or artificial lemonades, the polyuria ceases when the drink in question is limited.

Nervousness. The history and circumstances of the case, together with the absence of signs of gross disease of heart or kidneys, will be the main factors in deciding whether the polyuria is caused by excitement, nervousness, hysteria, or neurasthenia.

Epilepsy. The character of the convulsive seizures, their recurrence at intervals, and the influence of bromides upon them, will serve to diagnose epilepsy, for polyuria in association with the latter nearly always follows immediately after an attack of grand mal. It may, however, be associated with petit mal, or even be the chief phenomenon in some cases of epilepsy.

Migraine. The diagnosis of migraine depends on the history of the case and the absence of optic neuritis and other evidence of gross intracranial disease.

Asthma. Asthma is sometimes easy to diagnose, sometimes very difficult; it may be mistaken for recurrent bronchitis, cardiac dyspnoea, renal dyspnoea or uræmic 'asthma', mediastinal new growth, thoracic aneurysm, thymic 'asthma', laryngeal papilloma or fibroma, foreign body in the air-passages, syphilitic stenosis of a bronchus, goitre, or hysteria. It so frequently develops into emphysema and bronchitis that one is apt to

forget that the essential symptom of asthma is dyspnoea, and not cough. To diagnose a difficult case it may be necessary to examine the chest with the X rays to exclude aneurysm and new growth : to examine the larynx and vocal cords : the heart, the retinae, and the urine to exclude renal and cardiac mischief : and even then doubt may remain unless there is a clear and typical account of the nature of the earlier attacks in a patient who has had recurrences for years, and who is relieved by cocaine sprays to the nose, by ethereal tincture of lobelia, by inhalations of stramonium fumes, by injections of small doses of adrenalin, or by other anti-asthmatic remedies : Eosinophilia (p. 271) is more likely to be found during an attack of asthma than as the result of any of the other conditions that may simulate it. The polyuria occurs in by no means every case : when it does so, it generally follows immediately after an attack, and this applies also in cases of *angina pectoris*, the diagnosis of which is not difficult when the acute attacks of precordial pain radiate upwards and outwards to the left shoulder and down the left arm, and when there is evidence of an aortic lesion, or of atheroma and arteriosclerosis with high blood-pressure.

Periodic Polyuria, apparently without cause, is a condition which is regarded by some as a clinical entity : the diagnosis must always be difficult to be sure of, however, and the more carefully a cause is looked for, the fewer will be the cases remaining in this category : it will be found that some are due to epilepsy, others to secret drinking, others to granular kidney, others to hydronephrosis, and so on.

Hydronephrosis, with periodic emptying of the renal sac, is the chief cause of typically periodic polyuria. The diagnosis is arrived at by having the urine measured carefully each day, and by palpating the loins bimanually for evidence of renal enlargement. When a kidney swelling can be detected, and when this increases in size at the same time that less urine is being passed, whilst it materially decreases on the days when the polyuria occurs, the diagnosis of hydronephrosis or pyonephrosis is clear : and the distinction between the two depends on whether there is or is not pyuria. The commonest causes for hydronephrosis are movable kidney and renal calculus : and the X rays often serve to distinguish the latter from the former.

Fevers.—The polyuria that occurs during the cold stage of a malarial attack is replaced speedily by the opposite condition when the hot stage is reached : the diagnosis is afforded by the circumstances of the case, such as residence in a malarial district and previous attacks of the malady : by the discovery of malarial parasites in blood-films : by the absence of leucocytosis, the relative increase in the large hyaline corpuscles in the differential leucocyte count, and by the beneficial effects of quinine upon the disease. Polyuria during convalescence from other fevers, such as enterica or pneumonia, is not uncommon : it is a phenomenon that may attract some attention at the time, but it seldom gives rise to difficulty in diagnosis.

Edema and Diuretics.—The considerable polyuria that often results in renal or cardiac cases when oedema is clearing up under treatment is noteworthy, but the diagnosis is not, as a rule, difficult. If the polyuria is due merely to the excretion of accumulated fluid it will cease when there is no longer any oedema : whilst if it is due to granular kidney, or other underlying malady, it will continue even after the oedema has gone.

II. CAUSES OF CONTINUED POLYURIA.

1. Diabetes mellitus
2. Red granular contracted kidneys
3. Arteriosclerosis
4. Pale granular contracted kidneys
5. Lardaceous or amyloid kidneys
6. Cystic kidneys
7. Diabetes insipidus :
 - Due to no gross nervous lesion
 - Due to tumour or injury of the medulla oblongata
8. Incurable drinking of beer or spirits
9. Phosphatic diabetes
10. Azotic diabetes
11. Some cases of acromegaly
12. Some cases of myxoedema

Diabetes Mellitus. A very important step in the diagnosis is to examine the urine carefully. If sugar is present, a diagnosis of diabetes mellitus will be made, especially if diacetic acid and acetone are also present, and the specific gravity is between 1035 and 1045. Some authorities distinguish in kind as well as in degree between what they term true diabetes mellitus on the one hand and alimentary glycosuria or renal glycosuria on the other, though others hold that these differ only in degree. It is chiefly in severe diabetes of young people that polyuria is marked, something between 100 and 600 ounces of urine being passed per diem. In elderly people with glycosuria the polyuria is often slight: in these cases the specific gravity need not be above the normal, and diacetic acid and acetone are generally absent. If no sugar is present upon one occasion it may be on another, so that several examinations may be required.

Albuminuria. If albumin is present, and the polyuria cannot be attributed at once to anything so obvious as the clearing up of oedema or the administration of a diuretic, a careful microscopical examination of the centrifugalized deposit for renal tube-casts should be made: if the latter are absent, and if the patient is a young adult male who seems to be in good health, whose heart and other organs present no abnormal physical signs, and whose polyuria troubles him chiefly at times of excitement, for instance when he is in for an examination, the diagnosis is very likely to be that of 'functional' or 'physiological' albuminuria, in which case repeated tests will show that the urine is often quite free from albumin, especially the first thing in the morning, and the blood-pressure will not be raised. If, on the other hand, more than an occasional renal tube-cast was found, and the albumin and polyuria were persistent, the diagnosis of red granular contracted kidney, arteriosclerosis, pale granular contracted kidney, lardaceous kidney, or cystic kidney would suggest itself. The differential diagnosis between these is discussed under ALBUMINURIA (p. 8, et seq.).

Diabetes Insipidus. If neither albumin nor sugar is found, even on repeated testing, and if the polyuria is extreme and persistent, whilst the specific gravity of the urine is constantly low (1002 to 1006), a diagnosis of diabetes insipidus will suggest itself. Before this diagnosis is made finally, however, precautions must be taken to determine that the patient's thirst and polyuria are not due to habits of drinking to excess: it may be difficult to decide this in cases in which alcoholic beverages are consumed: but when the patient is a water-drinker, and yet cannot do with less than 8 or 10 pints a day, the drinking is probably a necessity, and not a habit: and diabetes insipidus is the probable diagnosis. In cases of doubt, the difficulty can be decided by restricting the intake of fluid and determining the specific gravity of the blood. This should be about 1056, and in a case where polyuria is due to drinking habits, restriction of fluids will not alter it materially: in a case of diabetes insipidus with restricted intake of fluids however, the drain of the latter from the blood still goes on, and the specific gravity rises to 1060, or 1065, unless the patient is allowed fluid by the mouth again.

There are two classes of diabetes insipidus, according as there is, or is not, a gross lesion of the central nervous system. If the malady follows on a fractured base of the skull, or if there are vomiting, headache, optic neuritis, or other symptoms of cerebral tumour, there is probably a gross lesion of the base of the brain in or near the medulla oblongata—thrombosis, softening, hemorrhage, small aneurysm, gumma, glioma or other neoplasm. In other cases, the complaint arises after a fright or shock, or even without any apparent cause, and there seems to be no gross lesion to account for it. A good many cases were met with during the war, the result as a rule of sheer funk, but persisting after the patients had returned to civil life. Presumably the cause in such cases lies in the nervous system, but without changes that are as yet recognizable even with the microscope. One remarkable feature of many such cases is the way in which the polyuria is checked by injections of pituitrin or of pituitary extract when more ordinary remedies fail.

Phosphatic and Azotic Diabetes.—A point that needs investigation in a case suspected of being diabetes insipidus is the amount of solids excreted daily in the urine. In ordinary diabetes insipidus the total solids are normal, the only increase being in the water. There are rare cases in which, in addition to polyuria, there is a great increase in the total solids in the urine also—so-called *baruria*. Rare though these cases are, they have been divided into two types, namely, those in which the inorganic salts are most increased—phosphatic

diabetes (p. 637) and those in which the nitrogenous constituents are augmented mainly azotic diabetes. The diagnosis here depends chiefly on quantitative estimation of the various urinary substances.

Acromegaly and Myxœdema.—It only remains to add that symptoms not unlike those of diabetes insipidus have sometimes arisen in cases of acromegaly and in myxœdema. There is probably a nervous factor in both cases, coupled in myxœdema with dryness of the skin, and consequent deficiency in perspiration; whilst in acromegaly there is the tumour-like enlargement of the pituitary body which may cause polyuria like any other lesion near the medulla oblongata. The diagnosis of acromegaly may be confirmed by the X rays, which will show the great enlargement of the bones of the hands, feet, and head, or even perhaps of the pituitary fossa itself (*Fig. 310*, p. 379); whilst in myxœdema, if the general symptoms, the pseudo-œdema of the legs, the acquired dullness of intellect, the increasing weight, and the broadening of the features (*Fig. 68*, p. 50), the fingers, and the hands, do not at once indicate the nature of the complaint, the beneficial effects of treatment by thyroid extract may serve to clinch the diagnosis. *Herbert French.*

POPLITEAL SWELLING. (See SWELLING, POPLITEAL, p. 844.)

PORPHYRINURIA.—(See URINE, ABNORMAL COLORATION OF, p. 902.)

PRECORDIAL PAIN. (See PAIN IN THE CHEST, p. 530.)

PRECORDIAL THRILLS. (See THRILLS, PRECORDIAL, p. 875.)

PRIAPISM signifies erection of the penis, continual, of troublesome degree, and not necessarily accompanied by sexual desire. Though generally spoken of in connection with the male sex, a precisely similar affection may occur in the female clitoris. The symptom is not often by itself of diagnostic importance; though it may be due to a considerable number of different causes, most of these need little more than enumeration. Three in particular merit special mention, however.

The first is priapism in elderly men: in some such cases there may be enlargement of the prostate, or local inflammation such as gouty urethritis, but in many the priapism seems to occur, without pathological cause, as a sort of final outburst of sexual energy before the onset of senile impotence.

The second special condition under which priapism may be extreme is after injury to the upper dorsal region of the spinal cord. The damage may be so serious as to have produced a fracture-dislocation of the spine with paraplegia, in which case the diagnosis will be obvious; short of this, however, there may have been only a minor degree of injury, with contusion and perhaps multiple small hæmorrhages into the substance of the cord, in association with which priapism may in some instances be very pronounced and last for weeks before recovery occurs.

The third is in connection with leukaemia: apart from any obvious change in the penis—cavernous hæmorrhage or the like—priapism has been noted as a prominent symptom both in splenomedullary and in lymphatic leukaemia, even before the other symptoms and signs have led to the diagnosis being made by blood examinations. The cause of the priapism in leukaemia is obscure, but the diagnosis will be suggested by the concomitant big spleen and confirmed by the great leucocytosis (pp. 32–35).

For the rest, the causes of priapism may be summarized briefly according to age periods, the chief being:

Priapism in infancy:—

Phimosis	Posthitis
Oxaluria	Calculus, urethral or vesical
Worms, especially <i>Oxyuris vermicularis</i>	Certain conditions of mental deficiency
Balanitis	Circumcision.

Priapism at puberty:—

The changes in the genital organs associated with the onset of puberty.

Priapism in young adult life :

Sleeping on the back
Non-emptying of the bladder when full
Ill-fitting trousers
Sexual excitement
Gonorrhœa
Epilepsy
After circumcision
Masturbation
Convalescence from an acute disease
Tetanus
Hydrophobia
Leukæmia
Thrombosis of the pampiniform plexus

Fracture of the dorsal spine
Transverse myelitis of the upper dorsal region
Spinal meningitis
Certain aphrodisiac drugs : —
Cantharides
Turpentine
Alcohol
Strychnine
Cannabis indica
Camphor
Phosphorus
Damiana.

Priapism in older men : —

The male menopause
Local irritation as the result of :—

Gouty urethritis Enlarged prostate | Hemorrhoids | A loaded rectum
Hemorrhage into the middle lobe of the cerebellum
Lesions of the pons varolii.

Very seldom indeed will priapism be the only symptom in the case : the diagnosis will be made from the history and from the other symptoms. *Herbert Freuch.*

PROLAPSE OF THE UTERUS. As a matter of practical fact, the uterus only descends as a result of a much wider displacement of all the movable structures which go to make up the pelvic floor. This is composed of a movable or pubic portion, and a fixed or sacral portion, and it is descent of the pubic portion which produces the actual lesion known as prolapse of the uterus. In other words, the uterus only descends because it is a part of the pubic portion of the pelvic floor. The uterus, bladder, and anterior vaginal wall are normally kept in position chiefly by the connective-tissue sheaths which accompany the blood-vessels supplying them, and it is injury and stretching of this connective tissue which allows of descent of the organs named. There is no doubt, however, that injuries to the fixed portion of the pelvic floor, the perineal body, and levatores ani muscles and their fasciæ will contribute something to the facility with which the structures mentioned may descend. In practice, therefore, prolapse of the uterus and descent of the pelvic floor lead to the appearance of a swelling at the vaginal orifice. There are other swellings which come down the vagina and appear at the vulva, and from them, therefore, prolapse of the uterus has to be diagnosed. These swellings are : (1) *Hypertrophic elongation of the cervix uteri* ; (2) *A tumour protruding from the vagina* ; (3) *Inversion of the uterus* ; (4) *Cystocele and rectocele* ; (5) *Extroversion of the bladder*.

1. Hypertrophy of the Cervix may be of the vaginal, the intermediate, or the supravaginal portion. The first is always congenital, and consists of elongation of the portio vaginalis. It may protrude from the vaginal entrance, but the vaginal fornices will be found unaltered at their usual level, and the sound will pass an increased distance proportionate to the length of the portio. The os uteri forms the apex of the protrusion. The fundus remains at its usual level. In hypertrophy of the intermediate portion the anterior fornix of the vagina is carried downwards with the cervix and may be obliterated, whilst the posterior fornix remains at its usual level, because the elongated portion lies between the insertion levels of the anterior and posterior vaginal walls. The sound passes an increased distance, and the os uteri forms the apex of the protrusion. The fundus remains at its usual level. In hypertrophy of the supravaginal portion *both* fornices are carried down with the cervix, and both may be obliterated. The bladder is displaced downwards, but the rectum does not descend. The fundus uteri will be found on bimanual examination to be at its usual level, whilst in true prolapse the fundus uteri descends as a whole with the rest of the uterus. It is common for some prolapse of the uterus as a whole to accompany elongation of the cervix, and this can be appreciated only by a careful bimanual examination.

2. A Tumour protruding into or from the vagina is most commonly a *fibromyoma of the uterus*. It may be a pedunculated growth either of the cervix, or protruding through

it, in either case hanging free in the vagina. It may grow from the cervix in the connective tissue in front, between the uterus, bladder, and anterior vaginal wall; or behind, between the uterus, rectum, and posterior vaginal wall; in either case the vaginal wall is stretched over the growth. The uterus will be felt high up. When the pedunculated growth is protruding from the os the hard ring of the cervix is felt encircling the pedicle. In the case of sessile interstitial growths, the cervix is high up in front or behind the growth, as the case may be, and if the tumour is a large one, may be out of reach altogether. In any case there is no descent of the uterus, and it may even be higher than usual. The tumour may be a *fibroid growing from the vaginal wall*, a *mucous polypus* of the cervix, a *cyst* of either vaginal wall, or a *malignant growth*.

3. Inversion of the Uterus may be chronic, or may occur immediately after labour as an acute condition which could hardly be mistaken for anything else, except perhaps extrusion of a fibroid immediately after delivery. In the latter case the tumour protrudes through the cervix, whilst the whole uterus can be felt above it bimanually, whereas in inversion the uterus turns inside-out, partially or completely, a cup-shaped depression is felt above instead of the rounded fundus, and a finger or the sound will only pass a short way by the side of the mass, or not at all if inversion is complete. Both conditions may be accompanied by hæmorrhage, but that with inversion may be exceedingly severe. Acute inversion is always accompanied by great shock, whilst extrusion of a fibroid is not. Chronic inversion is more likely to be mistaken for prolapse or a polypoid fibromyoma. It is distinguished from prolapse in that the uterus does not necessarily descend as a whole, the cervical ring is felt high up in its usual position, and the sound will only pass a short distance all round the protruding mass, according to the degree to which the uterus is inverted. A cup-shaped depression, instead of the rounded fundus, is felt in the vaginal vault by a hand on the abdominal wall.

4. Cystocele and Rectocele more often accompany prolapse of the uterus, but may occur independently of it. They are essentially bulgings of the anterior or posterior vaginal walls towards or through the vaginal entrance, the bladder or rectum being attached, and following them of necessity. A sound passed into the bladder, or a finger in the rectum, will directly enter the bulging vaginal wall, whilst the uterus will be felt bimanually above in its normal position.

5. Extroversion of the Bladder can occur either through a congenital defect in its wall, or through an injury to its basal portion: for instance, in removing a growth from the vaginal wall a gap may be left in the bladder through which extroversion may occur. The mucous membrane will be exposed in the vagina, and on it will be seen the two orifices of the ureters, with urine issuing by intermittent jets. The uterus in such a case may have its normal position.

T. G. Stevens.

PROPTOSIS. (See EXOPHTHALMOS, p. 283.)

PRURITUS. Itching may occur without visible lesions of the skin, save those due to scratching, or may be associated with various cutaneous eruptions. It is to the former condition that the word 'pruritus' should be restricted. The diseases of which itching is a symptom may be either neuroses, such as hysteria, hypochondriasis, and other affections of the nervous centres such as tabes dorsalis: or general nutritive disorders, such as diabetes mellitus, jaundice, and renal disease: or severe anæmias as in leukaemia and lymphadenoma. Severe itching is also a constant symptom of mycosis fungoides: or the irritation may be set up by the attacks of lice, scabies, fleas, bugs, or other parasites, or by definite skin lesions. Itching varies in character: it may be interpreted by the patient as a tingling, or pricking, or as a formication—a feeling as of insects crawling on the skin. It varies also in degree, from a mild sensation which is welcome to the patient from the pleasure he finds in scratching, to an irritation so severe and persistent as to endanger his life from sleeplessness, or his reason from the nervous irritability which it sets up. The affections in which itching is slight are seborrhœa, erythema, psoriasis, parapsoriasis, pityriasis rosea, pityriasis rubra pilaris, and pemphigus: it is more severe, in varying degrees, in eczema, prurigo, some cases of psoriasis, dermatitis herpetiformis, dermatitis gestationis, occupation dermatitis, lichen planus, lichenization, lichen urticatus, pityriasis rubra, mycosis fungoides, pityriasis rosea, cheiropompholyx, chilblain, prickly heat, tinea

marginata, urticaria, scabies, the various kinds of pediculosis, flea-, mosquito- and bug-bites, jellyfish and other stings. Even in the affections in which it is usually severe it varies much in degree in different cases. Itching seldom has any distinct diagnostic value, but in cases in which the cutaneous lesions may admit of more than one interpretation, its presence or absence may suffice to turn the balance. Syphilides hardly ever itch.

Pruritus proper may be general or local. Of general pruritus there are four varieties—pruritus universalis, pruritus hiemalis, pruritus senilis, and bath pruritus. The local varieties affect chiefly the anus, the vulva, and the scrotum, but the nares, the palms of the hands, and the soles of the feet may be the seat of the irritation. One of the most curious forms of pruritus is that which is associated with bathing. It affects most commonly the legs from the hips downwards; but the forearms also may be involved, and it may have even wider range. It is an affection of adolescence and adult life, and it is more frequent in males than in females.

If no lesions of the skin are present save those which can be accounted for, directly or indirectly, by the scratching, the diagnosis of pruritus is self-evident. Care must, however, be taken to exclude all possible sources of parasitic irritation; and it must always be remembered that lice and acari sometimes find harbourage in the most unexpected quarters. If the scratches are on the shoulders, or in the genital region, the presence of lice must be suspected; if on the wrists and between the fingers the burrows of the *Acarus scabiei* must be sought for. Some patients, without developing actual urticaria, suffer from severe itching after the ingestion of certain foods, notably strawberries, or crab. After serum injections pruritus may be extreme, especially about the ninth day, though urticaria generally accompanies it. Pruritus from the irritation of sugar (grocer's itch), or of *Primula obconica* or *Rhus toxicodendron* (gardener's itch), or of satin-wood sawdust (carpenter's itch), or of some kinds of soaps, or of the hairs of some caterpillars and moths, may or may not be associated with objective evidence of dermatitis. Only when careful investigation fails to reveal any local source of irritation should the case be diagnosed as one of pruritus pure and simple.

Ernest Dore.

PTOSIS is the term applied to drooping of the upper eyelid with inability to raise it to the full extent (Figs. 516-520); it must not be confused with the inequality of the palpebral apertures sometimes observed in people accustomed to screw up one eye.

Fig. 516. The patient's face at rest; there is complete ptosis from paralysis of the left levator palpebrae superioris. Note the scar of the healed gumma on the left cheek near the left angle of the nose.

Fig. 517. The patient is trying to look to his right; the left eyelid is being held up to show that the left eye is unable to look to the right owing to paralysis of the left internal rectus muscle.

Figs. 516, 517. PARALYSIS OF THE LEFT THIRD NERVE.

It is usually caused by *paralysis of the third nerve*, in which case it may also be associated with paralysis of other ocular muscles, either external or internal (Fig. 517). Sometimes it is accompanied by palsy of other motor cranial nerves, the 7th for instance

(Figs. 518 and 519), in which case the multiple cranial nerve paralyses immediately suggest a syphilitic cause, which may be verified in many cases by means of Wassermann's serum reaction.

Fig. 518. At test.

Fig. 519. With voluntary effort, which tends to show the voluntary nature of the case.

Figs. 518, 519. LEFT-SIDED NUCLEAR AND INFRANUCLEAR 7TH NERVE PARALYSIS AND COMPLETE PTOSIS FROM PARALYSIS OF THE LEFT 3RD NERVE, THE RESULT OF CEREBRAL SYPHILIS.

Fig. 520. Ptosis and enophthalmos of the left eye associated with distention of the superficial veins of the neck and left side of the thorax, the result of interference with the subclavian veins by a mediastinal lymphosarcoma which also involved and paralysed the left cervical sympathetic. The veins on the chest wall have been outlined with nitrate of silver.

In *paralysis of the cervical sympathetic*, slight ptosis may be associated with diminution in the size of the pupil on the affected side, and retraction of the eyeball or enophthalmos (Fig. 520). Ptosis also occurs in *myasthenia gravis* (Fig. 245, p. 291).

Ptosis of the lids, associated with much oedema and infiltration of the lids, is also found in all *inflammatory affections* of the conjunctiva, in *angioneurotic oedema* (Fig. 407, p. 513), and is a very constant symptom in *trachoma*.

Congenital ptosis is usually bilateral, and associated with smoothness of the upper lids and absence of all the usual cutaneous folds. The levator palpebrae is absent or ill-developed, and efforts to open the eye are made by the occipito-frontalis muscle.

Herbert L. Eason.

PTYALISM denotes excessive secretion of saliva. It is not easy, however, to determine in every case whether there is really excess, or whether the patient is merely allowing the normal saliva to dribble from the mouth. It is difficult to draw an absolute distinction, therefore, between dribbling of saliva and ptyalism,

though in practice the nature of the case may be obvious enough. One has but to consider the various conditions under which trouble with the saliva may arise to see how in some cases the difficulty is solely one of swallowing the normal secretion, as in bulbar paralysis and in babies; how in others there is both excess of secretion and difficulty in swallowing it, as in mercurial stomatitis; and how in others, again, there is too much secretion but no difficulty in swallowing it, as in functional or hysterical ptyalorrhœa. The first step in arriving at the diagnosis of the cause is to inquire carefully as to any *medicine or drug* the patient may be taking orally or applying externally, especially:—

Mercury	Iodide	Arsenic	Chlorate of potash
Pilocarpine	Bromide	Antimony	Cantharides
Jaborandi	Phosphorus	Aconite	Copper salts.

Mercury is the most important of these; its effects are worst when the mouth is not kept scrupulously clean, particularly when there is also nephritis, as is not uncommon in severe secondary syphilis. The saliva is also apt to have peculiar effects when mercury is being taken: thus, in repairing submarine cables it is customary to use saliva in completing the process of covering in the central core, and it has been found that if the repairer is taking mercury medicinally the repaired part of the cable speedily becomes defective again in a way which does not occur when the repairer is a healthy man taking no medicine.

If the salivation is not due to any drug it may be the result of one of the many forms of *general stomatitis*:—

Aphthous	Variculous	Due to angina Ludovici
Dyspeptic	Diphtheritic	„ cancrum oris
Septic	Syphilitic	„ pernicious anæmia
Suppurative	Tuberculous	„ hæmophilia
Ulcerous	Due to pyorrhœa alveolaris	„ sprue
Malignant	„ necrosis of the jaw	„ scurvy
		„ Vincent's angina.

The exact nature of a severe stomatitis will be diagnosed by making a careful local examination, ocular and digital, assisted by the history and, if need be, by bacteriological examination of swabbings from the mouth, by Wassermann's serum reaction for syphilis, or by microscopical examination of a fragment of the affected tissues. Tuberculous stomatitis is one of the rarer forms, but when it occurs it is severe: it may be primary, but more often is associated with obvious phthisis.

If drugs and general stomatitis can be excluded, local examination may still serve to detect a local cause acting by reflex irritation of the fifth nerve especially:—

A jagged carious tooth	A ranula
A rough filling	A gumboil
A stump left beneath a tooth-plate	An epulis
A broken or ill-fitting tooth-plate	A myeloid sarcoma of the jaw
A foreign body, such as a fishbone, impacted in the gum	A salivary calculus
Neuralgia of the fifth nerve	An eschar left by some recent irritant or corrosive substance, or injury.

If careful examination serves to exclude all these, the salivation, apparent rather than real, may be found to result from *mechanical difficulties in swallowing*, the effect of such lesions as:

Mumps	Gumma of the palate
Acute tonsillitis	Gumma of the pharynx
Quinsy	Primary chancre of the tongue
Epithelioma of the tongue	Primary chancre of the tonsil
Epithelioma of the jaw	Actinomycosis of the tongue
Epithelioma of the tonsil	Actinomycosis of the jaw
Epithelioma of the palate	Fracture of the jaw
Epithelioma of the pharynx	Dislocation of the jaw
Sarcoma of the tonsil	Fixation of the jaw, as by osteo-arthritis of the temporomaxillary joint
Fibrosarcoma of the basisphenoid	Painful affections of the larynx, pharynx, or œsophagus.
Cervical caries	
Retropharyngeal abscess	
Gumma of the tongue	

In the absence of any obvious structural lesion locally, it may yet be clear that inability to swallow, owing to paralysis of some kind, is the cause of the apparent salivation, for instance in cases of :—

Bulbar paralysis	Myasthenia gravis	Paralysis agitans
Pseudo-bulbar paralysis	Hypoglossal nerve paralysis	Hydrophobia
Bilateral facial paralysis	Diphtheritic paralysis	Botulism.

The differential diagnosis of these conditions is discussed elsewhere, and of them all it is only in bulbar and pseudo-bulbar paralysis that the dribbling of much saliva is a prominent symptom. The sequence of events summarized by the term labio-glosso-pharyngo-laryngeal paralysis is sufficiently characteristic as a rule : pseudo-bulbar paralysis, being of cortical instead of medullary origin, has not the wasting of the tongue that is prominent in the latter.

The salivation that results from *gastric* or *hepatic reflexes* is almost physiological, though sometimes it reaches a pathological degree in certain cases of :—

Dilatation of the stomach	Acute dyspepsia	Biliousness
Gastric ulcer	Acute gastritis	Hepatic disorder
Duodenal ulcer	Gastric carcinoma	Pancreatitis.

Mere slovenliness and lack of proper cerebral control are responsible for the slobbering and salivation of :—

Idiots	Imbeciles	Demented and other mental cases.
--------	-----------	----------------------------------

Finally, a remarkable degree of salivation can sometimes be attributed to nothing but functional disorder—*ptyalorrhœa*. It may occur in men as well as in women, generally in later life rather than at a time when hysteria is commonest. The condition is a sort of salivary neurosis, which may come on suddenly and without obvious cause, or as the result of some worry, shock, or mental emotion. It may possibly be a functional affection of the fifth nerve analogous to the far more distressing *tic douloureux*. It is sometimes prominent amongst the neuroses that are apt to accompany pregnancy. It can only be diagnosed when a careful examination has served to exclude any likelihood of organic disease, when the history is suggestive, and when the excessive salivation ceases after a time almost as suddenly as it began. In some male cases, notwithstanding the diagnosis being 'functional', a high blood-pressure will be found, with other signs of arteriosclerosis, suggesting that errors in the circulation involving the vasomotor and other brain centres are responsible for the symptom.

Herbert French.

PULSATING TUMOURS. (See SWELLING, PULSATILE, p. 846.)

PULSATION, UNDUE ABDOMINAL AORTIC. Excessive pulsation of the abdominal aorta may occur in cases of aortic regurgitation, when all the arteries throughout the body may pulsate with undue violence. Apart from aortic regurgitation, however, it is nearly always an entirely functional disorder of the aorta. It occurs much more frequently in women than in men, the patients generally being unmarried or childless, between 20 and 40 years of age. They complain of pain in the abdomen, especially in the epigastrium ; a feeling of discomfort and distress ; a sensation of pulsation and throbbing over the abdominal aorta ; nausea, retching, sickness, and constipation ; they are usually thin, anæmic, extremely nervous, often hysterical, and sometimes decidedly hypochondriacal. There may be nothing else the matter with them at all, or they may be suffering from some other complaint of which much nervousness is a feature—exophthalmic goitre, for example. The condition is frequently associated with movable kidney and enteroptosis, the diagnosis of the latter being confirmed by bismuth and X-ray examination, and the patient may be relieved by wearing a suitable abdominal support ; the symptoms may suggest some organic disease, such as gastric ulcer, appendicitis, duodenal ulcer, gall-stone, renal stone, or ovaritis, without any of these being present.

On palpation of the abdomen the pulsation may be found to be forcible ; but the normal cylindrical outline of the aorta can generally be felt to be quite free from any sacular bulging or fusiform dilatation ; there is no thrill over it ; on applying a stethoscope

lightly to the pulsating region no murmur will be audible, but firmer pressure, sufficient to compress the aorta slightly, will bring out a systolic bruit. The heart, lungs, and urine are usually normal. The knee-jerks are apt to be much exaggerated, though the plantar reflexes remain flexor and there is no ankle-clonus. The chief importance of the condition clinically is that it is apt to be mistaken for an aneurysm of the abdominal aorta. Abdominal aneurysm is so extremely rare in women, however, that it should never be diagnosed unless the pulsation can be made out to be definitely expansile, or unless, in addition to pulsation, a definite swelling of the aorta can be felt.

Herbert French.

PULSE, IRREGULAR. No advance in clinical medicine is more striking than the change which has come over our view of the arrhythmic pulse during the past twenty years. Formerly we felt that our duty was finished when we had recorded the main facts as to whether the force or the frequency varied, or both, and so forth. Now, however, it is possible to refer almost every type of irregularity to a definite cause, and thus to gain information of the utmost value for prognosis and treatment. To this end it is advisable that each case should be investigated by means of graphic methods, or, at all events, so to familiarize oneself with those methods as to be able to conjure up a mental picture of the appropriate record whenever one is confronted by an arrhythmic pulse. The two chief instruments available for the purpose are: (1) *The polygraph*; and (2) *The electrocardiograph*. Most practitioners, however, are obliged to learn what they can about their patient's heart without these means, and in what follows this has been borne in mind.

1. **The Polygraph**, of which there are several good makes, consists of: (a) A clockwork machine drawing a band of paper at a uniform rate over a flat surface; (b) Tambours for application to different parts of the body where there is superficial pulsation; (c) Levers connected by tubing with these tambours, carrying pens at their free ends which write on the travelling paper; (d) A time-marking lever, also driven by clockwork, usually marking five times per second. As a general rule one of the tambours is applied to the radial artery, the other to the internal jugular vein at the root of the neck. The result (*Fig. 521*) is a synchronous record of (i) time, (ii) the movements of the radial artery, (iii) the movements of the jugular vein. In the records from this last, each cardiac cycle exhibits three principal waves. By comparison with the radial trace the identity of the ventriculo-systolic wave (c) is established. The wave immediately preceding this is the auriculo-systolic (a), and the interval between its origin and that of the ventriculo-systolic, normally about 0.2 second, is spoken of as the 'a c interval'. It constitutes an index of auriculo-ventricular conductivity. The third, or r wave, arises at the end of ventricular systole. The chief value of the method lies in the accuracy with which it enables us to study the time relations of auricular and ventricular systole.

Fig. 521.—Normal polygram. a, Auricular systole; c, Ventricular systole. A, Time marker in $\frac{1}{5}$ sec.; B, Jugular vein record; C, Radial pulse record.

The wave immediately preceding this is the auriculo-systolic (a), and the interval between its origin and that of the ventriculo-systolic, normally about 0.2 second, is spoken of as the 'a c interval'. It constitutes an index of auriculo-ventricular conductivity. The third, or r wave, arises at the end of ventricular systole. The chief value of the method lies in the accuracy with which it enables us to study the time relations of auricular and ventricular systole.

2. **The Electrocardiograph.** The action of the electrocardiograph depends on the fact that muscle undergoing excitation is an electrical battery, the currents in which can be appreciated and their movements recorded by a sufficiently delicate galvanometer. The contracting heart generates currents which are led off to an extremely sensitive galvanometer, and the photographic records made from this can be interpreted in terms of cardiac movement (*Fig. 522*).

Fig. 522.—Normal electrocardiogram. P, Stimulation and contraction of the auricles; QRST, Stimulation and contraction of the ventricles.

There is one form of pulse irregularity, the 'pulsus paradoxus', or disappearance of the arterial pulse during inspiration, which is due solely to extracardiac causes. A certain significance attaches to it since it is occasionally observed in cases of pericardial effusion or adhesion; but it may also be due to compression of the subclavian artery between the first rib and the clavicle during inspiration. In such a case a jet-like systolic bruit is heard over the subclavian area, during inspiration, or on abduction of the arm to a right angle or more from the body.

But, for the most part, the significance of irregularities of the pulse lies in the information that they afford as to perversions of the myocardial functions. It is necessary, therefore, to know the normal course of those functions. The heart generates its own stimuli: these normally arise at the sinu-auricular node, a relic of the primitive cardiac tube lying at the junction of the sinus venosus with the right auricle; thence they pass through the auricular walls and are conducted along the auriculo-ventricular bundle of His, a narrow strip of muscle—also a relic of the primitive cardiac tube—into the ventricular walls, one branch from the stem of the main bundle running to each ventricle; each portion of the cardiac muscle contracts as this stimulus provokes it to do so, the result being a co-ordinated and economical movement of the whole heart.

Pulse irregularities may be caused by: (1) *Variations in the rate of stimulus production at the normal point of origin, the sinu-auricular node*; (2) *Interference with the spread of the stimulus through the walls of the heart*; (3) *Dislocation of the site of stimulus production (premature beats or extrasystoles, paroxysmal tachycardia, idioventricular rhythm)*; (4) *Abnormalities in the contraction consequent on normal stimulation (alternating pulse)*.

1. Variations in the Rate of Stimulus Production of the Sinu-auricular Node. Sinus irregularity is specially common in children and nervous subjects, in convalescence and acute illness, and in the presence of increased intracranial pressure. It is a normal phenomenon in childhood. A certain amount of variation in pulse-speed is perceptible in most persons in connection with breathing, inspiration slowing and expiration quickening the pulse; and also under the influence of emotion. To this last fact are to be ascribed most of the cases of 'disordered action of the heart' seen during and since the war. In most persons, variations of this kind are in the direction of 'irritability' of the heart, i.e., the accelerator mechanism is unduly excitable, but in a few the pulse is retarded with

Fig. 523. Electrocardiogram from a case of sinus arrhythmia. The QRS-T sequence is followed by each beat, but the whole beat varies in length, the variation showing a tendency to wax and wane in an orderly manner. Time-markings in $\frac{1}{2}$ and in $\frac{1}{4}$ sec.

indue case. The difference in length between two sequent beats is never great, and sufficiently prolonged observation is nearly always rewarded by the discovery of a 'dominant rhythm'—i.e., a normal rhythm—from which the pulse departs from time to time. This type of irregularity is singularly apt to be exaggerated by excitement, and by bidding the patient swallow or hold his breath. As it does not depend on intracardiac causes, physical examination of the heart detects no sign of disease. It is generally possible to distinguish it from other forms of irregularity without instrumental help; but sometimes it is difficult to be quite sure that the arrhythmia is of this type, and if a tracing be taken (Fig. 523), it shows that auricular and ventricular systole are following each other in normal sequence.

2. Interference with the Spread of the Stimulus through the Cardiac Walls causes several kinds of arrhythmia.

a. There is a rare form in which the spread of the stimulus from the sinu-auricular node to the auricular muscle is inhibited by influences the nature of which is unknown except that it occasionally occurs under treatment by *digitalis*. The chief clinical feature of this arrhythmia is an irregular dropping of beats. This awakens a suspicion of auriculo-ventricular block (see below), and it is only by means of graphic records that this suspicion

is dispelled. These (Fig. 524) prove that the beats that are dropped are beats of auricle as well as ventricle: the stimulus has been stopped, not between auricle and ventricle as in the traditional heart-block, but before even the auricle was reached. That, at all events, is the hypothesis at present accepted by way of explanation of these cases in which beats of the whole heart, auricle as well as ventricle, drop out, and it is on this hypothesis

Fig. 524. Polygram illustrative of 'intra-auricular block'. At several points (X) there is a gap in the pulse practically equivalent to the dropping of a whole beat. The radial curve shows that the auricular beat is also dropped; i.e., the whole heart has missed a beat. On the 'intra-auricular block' hypothesis this is due to blocking of a stimulus in its passage from the intra-auricular node into the auricular walls. An alternative explanation is that the stimulus for such beats (or, at times, being inhibited by the intra-auricular node or by extracardiac influences). A, Time marker in $\frac{1}{100}$ sec.; B, Auricular vein curve; C, Radial artery curve.

that the term '*sinu-auricular block*' has been generally accepted. The recognition of this form of arrhythmia is important only as a means of distinguishing between it and the much more serious auriculo-ventricular block.

b. There are two types of arrhythmia that arise from disturbance of the spread of the stimulus through the auricular walls. Ordinarily this should diffuse evenly throughout the musculature of the two auricles: from which it is gathered together into the upper end of the auriculo-ventricular bundle prior to its journey through this latter. But in *auricular flutter* this orderly sequence is replaced, either continuously or in paroxysms, by one in which the auricle is stimulated at a great rate—round about 300 times per minute—responding to each stimulus, and therefore beating, regularly or nearly so, at a corresponding speed. Usually half these beats are blocked at the auriculo-ventricular junction, the result being a regular pulse of 150 per minute: occasionally only a quarter of the beats reach the ventricle, the result being a regular pulse of 75 per minute. Particularly in this latter case, but also in the former, it is impossible to be sure of the presence of auricular flutter without graphic records, preferably an electrocardiogram (Fig. 525).

A more serious degree of interference with the transauricular passage of the stimulus, and one which is practically always associated with serious auricular disease, is that known as *auricular fibrillation*. The resulting irregularity is the 'total' arrhythmia which is so characteristic of breakdown of the auricles. This is essentially a terminal phase of

Fig. 525. Electrocardiogram of a heart in auricular flutter. PPP, Auricular beats, about 280 per minute; QRS, Ventricular beat, about 70 per minute. Three out of every four auricular beats are 'blocked' in their passage from auricle to ventricle. Only one beat in four succeeds in reaching and stimulating the ventricle. Time markings in $\frac{1}{100}$ and $\frac{1}{500}$ sec.

the chronic organic diseases, especially of mitral stenosis and cardiosclerosis: it may be prolonged for years, but nevertheless it marks a certain 'last state' of the auricular musculature. The features which characterize it are of two kinds: those which mark the disappearance of auricular systole, and the evidences of absolute irregularity of the pulse. To the observer using ordinary methods of examination without apparatus this latter is the more obvious and striking side of the picture. If the pulse is counted for one or two minutes it will be found that there is no 'dominant' rhythm: anarchy is complete. The pulse is usually hasty—over 100 per minute—but not always. The heart's action is similarly irregular, and on comparing it with the arterial pulse a certain number of beats too feeble to reach the wrist will be discovered. Cessation of effective auricular

systole is manifested in two ways if the case be one of mitral stenosis : by disappearance of the presystolic thrill and bruit (the diastolic vibration, however, persisting), and by disappearance of the auriculo-systolic wave from the jugular tracing. Of course, if the case is not one of mitral disease, there are no presystolic vibrations to disappear. How-

Fig. 526.—Polygram to illustrate ‘auricular fibrillation’. Note the complete irregularity of the beat, and the entire absence of auriculo-systolic waves from the jugular curve. A, Time marker in $\frac{1}{2}$ sec.; B, Jugular ven curve; C, Radial pulse curve.

ever, the absolute disorder of the pulse, coupled with evidences of organic disease of the heart and a gravely embarrassed circulation, combine to form a picture so characteristic that there is little fear of a mistake. Nevertheless, there are cases of sinus irregularity so profound that without a polygraph tracing it is difficult to exclude auricular fibrillation :

Fig. 527.—Electrocardiogram to show auricular fibrillation. PPP, Auricular fibrillation, irregular in rhythm, at a speed of over 400 per minute; QRS, Ventricular beat, absolutely irregular in rhythm, at about 50 per minute. The time markings are in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

the same may be said of some few cases of multiple extrasystolic irregularity. The salient features of this kind of arrhythmia are clearly seen in Figs. 526 and 527. In the latter are seen evidences of fibrillary movement of the auricles which has given a name to this syndrome.

Fig. 528.—Incomplete heart-block. Note at x: (i) The radial pulse misses a beat entirely; (ii) The jugular pulse has a wave without a sequent C wave. This means that auricular systole occurred at the normal interval after the preceding auricle cycle but that ventricular systole failed to follow; the reason being that disease implicating the conducting paths hindered the normal transmission of stimuli from auricle to ventricle. Note at xx The long C-interval (about 0.4 seconds), indicating considerable though incomplete hindrance to transmission of the impulse from auricle to ventricle.

Heart-block is of various grades. The mildest type is that in which the interval elapsing between the start of auricular systole and that of ventricular systole is prolonged

Fig. 529.—Electrocardiogram from early heart-block. Note that the P-R interval increases in length, till the sixth auricular beat in the sequence entirely fails to get through. This is due to an increasing ‘fatigue’ of the auriculo-ventricular bundle. The time markings are in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

(Figs. 528 and 529) ; this, of course, can only be detected by graphic records of the arterial and venous pulses or electrocardiograms. The next grade, in which some of the descending

impulses are completely 'blocked' in their passage from auricle to ventricle, reveals itself in ordinary observation of the pulse as a dropping of beats; a gap, equivalent in length to two whole pulse-beats, separates one beat from that which preceded it. Here the auricle has contracted in the ordinary way, but since the stimulus which provoked that contrac-

Fig. 529. Electrocardiogram of partial heart-block. PP, Auricular beats, regular at 70 per minute; RST, Ventricular beat, regular at 33 per minute. Only half the stimuli pass through to the ventricles, every alternate one being 'blocked' in the auriculo-ventricular bundle.

tion has not passed into the ventricle, the latter has failed to contract (see *Figs. 528 and 529*). This proves that there is some disease or disorder of the conducting apparatus. In higher grades of block, every third, or every other stimulus, or even two out of three, or three out of four, may fail to pass over from auricle to ventricle (*Figs. 530 and 531*);

Fig. 531. Heart-block. The ventricle only responds to every fourth stimulus descending to it from the auricle. The *a*-interval is more than twice its normal length. A, Time marker in 1 sec.; B, Radial tracing; C, Jugular tracing.

so that the auricle may be beating 72 to the minute while the pulse counted at the wrist comes to 48, 36, 24, or 18 only. In the highest grade of all the auricle is completely dissociated from the ventricle, which assumes a rhythm of its own, usually at 30 to 40 per minute: thus the auricle is beating regularly at one rate, and the ventricle at another

Fig. 532. Electrocardiogram to show complete heart-block. PPP, Auricular beats, regular, at 100 per minute. RST, Ventricular beats, regular, at 42-43 per minute. The auricular and ventricular rhythms are independent of each other.

quite independently of that of the auricle (*Fig. 532*). This ventricular rhythm is often called 'idioventricular rhythm'.

To make sure that a dropped beat, or a slow regular pulse, is due to heart-block, it is necessary to prove that the auricle has contracted while the ventricle failed to follow suit. The only means of such proof, apart from the use of the polygraph or the electrocardiograph, is furnished by observation of the venous pulse in the neck. If this can be seen to continue regularly, during the radial pauses, as well as immediately before the radial beats, then it is safe to assume that the condition is one of heart-block. It must be confessed, however, that this is very often difficult, and sometimes impossible, and that the observer is on much firmer ground if he obtains solid proof of his suspicion in the form of a graphic record. This will show that in the intervals when the pulse failed at the wrist, the wave which represents auricular systole made its appearance at the proper moment in the jugular curve (see *Fig. 528*). It is particularly desirable to obtain graphic

evidence when it is a matter of accounting for occasional failures of the radial beat : for, as will be shown below, this grade of block may be simulated by extrasystoles too feeble to reach the wrist (see *Fig. 533*), and also in extreme exhaustion of contractility.

In the higher grades of block the patient often suffers from severe syncopal and epileptiform attacks, the coincidence of which with heart-block constitutes the Stokes-Adams syndrome. On these attacks the pulse usually becomes slower than ever. It is not quite safe, however, to conclude from the coincidence of such attacks with slow pulse that a lesion of conductivity is present : a similar syndrome may arise as a consequence of sinu-auricular block (see p. 665). The distinction between this condition and that of

Fig. 533. Ventricular extrasystole. Note at *x* a small premature radial beat : this coincides with a large wave (*c*) in the jugular curve. *c* is therefore a ventriculo-systolic wave, and as it is not preceded by any auricular movement, it denotes a premature contraction, or 'extrasystole', arising in the ventricle. Clinically this case simulated heart block until the tracing made the truth plain. The following points should also be noted : (*a*) The premature beat is followed by a compensatory pause, so that the pair of beats of which the premature beat is the first is equal in duration to a pair of normal beats ; (*b*) The beat that follows the compensatory pause is of an amplitude greater than the normal ; (*c*) Following this larger beat there is a period of 'alternation' of the radial pulse.

heart-block is important, for the latter signifies organic disease of the heart, while the former does not : and their distinction cannot be safely founded except on the evidence of graphic records.

If the existence of heart-block be definitely proved, it points practically always to the existence of organic disease implicating the bundle which connects auricle with ventricle. Heart-block may arise in connection with acute infections such as diphtheria, rheumatism, influenza, pneumonia, or ulcerative endocarditis : or as part of chronic disease such as gumma, neoplasm, or cardiosclerosis. In any given case the cause of the block can only be determined by a general consideration of all its features.

3. Dislocation of the Site of Stimulus Production. —

a. Turning to those forms of irregularity which are due to ectopic generation of stimuli, one finds that the simplest type, the *extrasystole*, is very common. It is associated with nervous states and with senile cardiac sclerosis, and even in the latter association is of no great import, since it occurs as often in the mild as in the severe grades of degeneration. Yet it is often productive of uncomfortable sensations which distress and alarm the patient : it is therefore necessary to recognize its nature in order that a reassuring statement may be made. The extrasystole is "a premature contraction of auricle or

Fig. 534. Electrocardiogram displaying 'bigeminy' (i.e., every other beat is a premature beat or extrasystole, arising in the ventricle). *PQRST*, Normal beat ; *Q'R'S'T'*, Premature beat arising in the ventricle. The time markings are in $\frac{1}{10}$ and $\frac{1}{20}$ sec.

ventricle in response to a stimulus from some abnormal part of the heart, where otherwise the fundamental rhythm of the heart is maintained" (Mackenzie). These premature beats may arise either in the auricular or in the ventricular wall, or (much more rarely) in the junctional tissues. Their precise mode of origin is unknown.

The patient sometimes complains of feeling as if his heart had stopped, and then gone on again with a jerk : or it may be that the jerk alone is felt. The observer, with his finger on the radial pulse, feels a small beat occur before its time, i.e., at a shorter interval after the preceding beat than the usual pause between beats. The beat which follows this premature one is generally more forcible than normal : in some cases it follows after a

compensatory pause, i.e., a pause of such length that it makes up for the brevity of the premature beat, the two together being equal in duration to two normal beats (*Fig. 533*).

Fig. 533. Electrocardiogram showing a premature contraction arising in the auricle (auricular extrasystole). PQRST, Normal beat; P'Q'R'S'T', Premature beat. Note the abnormal (downward) direction of P'. This is not a constant feature of auricular premature beats. The time markings are in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

It is the small premature beat which signifies the occurrence of an extrasystole (*Figs. 533-537*). Confirmatory evidence of its nature may often be found in the heart-sounds :

Fig. 534. Electrocardiogram showing a premature contraction arising in the ventricle (ventricular extrasystole). PQRST, Normal beat; Q'R'S', Premature ventricular beat. The time markings are in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

Simultaneously with the small premature beat at the wrist, a premature feeble pair of heart-sounds (or in some cases the first sound only) is heard.

It might be argued that if the extrasystole can be thus detected by ordinary methods of examination, and that if it has little positive significance in assisting to a full diagnosis of the case, it is needless to apply graphic methods to its elucidation : it is certainly

Fig. 537. Electrocardiogram showing multiple ventricular extrasystoles, each normal ventricular systole being followed by a premature ventricular extrasystole. From a lady, age 70, whose only complaint was an increasing tendency to shortness of breath on exertion. Time markings are in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

true that it is of all forms of irregularity the one in which tracing is least essential, but there are one or two considerations which may make a tracing advisable and even necessary : (i) The premature contraction may be so small that its beat is not felt at the

wrist : a dropped beat may be thus simulated, especially where the extrasystole is followed by a compensatory pause : in such cases heart-block may be wrongly diagnosed unless clearer information be sought in a tracing : this will show the fault to be due to a feeble premature beat, and not to a blocked auricular impulse (see *Fig. 533*). (ii) Extrasystoles may occur in complexes, e.g., at every second or third beat. In the former case an alternation will result : a full beat is followed at a short interval by a small beat, and this after a long interval by a full beat, and so on (pulsus bigeminus, *Figs. 534, 537*). The true nature of such an arrhythmia is much easier to appreciate when it is seen mapped out in a tracing. (iii) A polygraphic or electrocardiographic record (*Figs. 535, 536*) enables the observer to discover whether the premature beat arose in the auricle, in the ventricle, or in the junctional tissues. In the first case the curve shows an auricular wave preceding the premature arterial beat at the proper interval ; in the second case there is no such auricular wave : while in the third case auricle and ventricle contract simultaneously, and the result is an abnormally large wave in the jugular curve. A knowledge of the source of extrasystoles may occasionally be of material value : for instance, in mitral stenosis the final breakdown of the auricle is sometimes heralded by a series of extrasystoles of auricular origin. It is true that as a rule auricular extrasystoles are not followed by a compensatory pause, while those of ventricular origin are : but it is not always easy to appreciate this distinction apart from a tracing, and, moreover, it does not invariably hold good.

b. In paroxysmal tachycardia, as the term is used nowadays, the patient suffers from attacks of fast but regular cardiac action. The duration of these may vary from seconds to days ; what is characteristic is the abrupt transition from the normal to the rapid rhythm and back again, at the onset and offset of the attack. The patient is conscious of discomfort, and indeed there is good cause if the speed is above a certain pitch : for in such a case the auricle gets no time for emptying itself, and becomes over-distended, pulmonary stagnation with cyanosis and venous engorgement resulting. Tachycardial paroxysms may appear on a background of organic disease, cardiosclerosis and mitral stenosis in particular : or the patient's heart may be normal. This form of irregularity has especially to be distinguished from the total arrhythmia of auricular fibrillation, which may manifest itself in paroxysms, particularly in its earlier stages. In true paroxysmal tachycardia the pulse is regular, whereas in the other it is quite irregular.

The quick pulse of auricular flutter is also very like that of paroxysmal tachycardia, but its duration is longer, and its speed seldom exceeds 180, while that of paroxysmal tachycardia often does.

By means of a polygraph tracing it is possible to discover the source of the rapid rhythm, whether it is auricular or ventricular, in many cases. In others, an electrocardiogram is necessary (*Fig. 538*), or, at all events, worth while whenever it is possible. Usually the abnormal rhythm is then seen to arise in the auricle. Rarely, however, it is ventricular in origin, and the prognosis is much worse in such cases.

Fig. 538. Electrocardiogram from paroxysmal tachycardia. Lead 2 only is shown. The heart is beating regularly at a rate of over 180 per minute. The time-markings are in 1 and 1/2 sec.

c. The idioventricular rhythm has already been described under heart-block. It is a slow, regular rhythm which arises in or below the auriculo-ventricular junctional tissues when these latter have been so injured higher up that they no longer transmit stimuli from auricle to ventricle. Its rate is not affected by exercise or excitement. There is an absolute lack of harmony between the jugular and the radial pulses ; each

beats regularly at its own speed. Often it is possible to detect this disharmony without graphic records, but a polygram sets the observation on a more secure basis: and an electrocardiogram traces the matter to its foundation by showing auricular beats at one speed per minute and ventricular beats at a quite different one (see *Fig. 532*).

4. The Stimuli are Regular, but the Response to them varies in Amplitude.—The term 'pulsus alternans' is reserved for cases in which beats, equal in length, alternate in force; that is, for an alternation of a large beat with a small beat, but not of a long beat with a short beat. This phenomenon is an expression of exhaustion of the contractile power of the ventricle, and it is therefore of serious import. In some instances it can be detected clearly with the finger on the pulse: a full wave is followed by a small wave, and this again by a full wave, and so on, each beat being of equal duration. Often, however, the difference in the amplitude of the waves is minute, and in such circumstances the sphygmomanometer is a more delicate index than a graphic record. What it shows is that the systolic or maximal pressures alternate. For example, the 'odd' pulse waves reach a pressure of 150 mm. Hg as their maximum, while the 'even' ones attain a height of 145 mm. only. Careful use of the sphygmomanometer will prove this, for if the pressure within the armlet be at 148 mm., it will just suppress the weaker beats, while still allowing the stronger beats to pass through. What actually happens is that if the armlet be over-inflated and then slowly deflated, the sounds heard over the bend of the elbow will pass through a brief phase in which only half of them are heard, the other half becoming audible soon after as the pressure in the armlet falls. When these first become audible the alternation between them and the stronger beats is for a moment quite obvious, till further lowering of the armlet pressure abolishes the distinction. Other signs of ventricular failure are usually present. Sometimes, however, alternation may be present only when the heart is hurried, or in paroxysmal tachycardia, or after premature beats (see *Fig. 533*). The later progress of the case may or may not be such as to render this alternation continuous and permanent. In connection with this form of irregularity it is important to note that the smaller beat may sometimes be so feeble as to fail to reach the wrist: consequently the pulse appears to drop a beat.

SUMMARY OF VARIATIONS IN RHYTHM OF PULSE.

1. *The radial pulse may be wholly regular, but abnormally slow or abnormally quick.*

1. Regular Slow Pulse may be due to:—

1. *Extracardiac* causes (convalescence from acute illness, sinus irregularity, raised intracranial pressure, jaundice). In such, the whole heart is slowed, auricle and ventricle alike, and there are no signs of cardiac disease.

2. *Intracardiac* causes. (a) *Alternating extrasystoles* may cause an apparent regular slowing of the pulse: if each 'normal' beat is followed by a premature one too small to be felt at the wrist, the radial pulse will appear slow. The real interpretation may be discovered by a graphic record (*Fig. 534*), and by comparing the heart-sounds with the pulse at the wrist: by these means the occurrence of a small premature beat after every normal beat will be observed. (b) *Heart block*, either partial or complete, will render the radial pulse slow. If the block be partial but regularly recurrent, the pulse at the wrist will be regular and slow: e.g., if the auricle is beating at 72 per minute, and every other stimulus is blocked in its passage from auricle to ventricle, a regular pulse of 36 per minute will be the result (*Fig. 530*): while if two out of every three stimuli are blocked, the pulse will beat regularly at 24 times per minute. If the block be complete (*Fig. 532*), auricle and ventricle will each have its own regular rhythm: that of the ventricle is usually at the rate of 30 to 40 per minute, and this will accordingly be the rate of the pulse. The occurrence of epileptiform and syncopal attacks is to a large extent confirmatory of the diagnosis of heart-block: but as mild attacks of this kind may occur in sinu-auricular block (see p. 665), this cannot be accepted as proved unless it has been demonstrated that when the auricle contracts, the ventricle sometimes or always fails to follow suit. This evidence is provided (i) by naked-eye observation of the jugular, i.e., auricular movement, (ii) by auscultation detecting auricular sounds during the ventricular pauses, (iii) by polygraph records, which not only afford conclusive evidence, but also facilitate the study of the degree of block present, (iv) by electrocardiograms.

B.—Regular Rapid Pulse (and see TACHYCARDIA, p. 856) may be due to:—

1. *Extracardiac* causes (tuberculosis and other infections, excitement, Graves' disease, etc.). Here the whole heart is persistently hurried, and the cause is usually manifest; moreover, change to or from a slower rate is gradual and not abrupt.

2. *Intracardiac* causes. The only important intracardiac conditions giving rise to a quick but regular pulse are: (a) That form of ectopic stimulus production which manifests itself in *paroxysmal tachycardia*: here there may or may not be other signs of cardiac disease; the tachycardia is temporary, its onset and cessation being abrupt; and (b) *Auricular flutter*, which causes a regular tachycardia at about 150 to 180 per minute, occurring in long periods rather than short paroxysms.

In a differential study of these kinds of tachycardia graphic records are of the greatest help, and indeed most cases of auricular flutter would escape recognition unless submitted to electrocardiographic scrutiny.

II. —*The radial pulse may show a fundamental regularity, occasionally interrupted by premature beats, intermissions, or periods of irregularity.*

1. **Premature Beats** (extrasystoles) may be single or multiple; they may occur at regular or irregular intervals; the pause following them may or may not be compensatory; the beat next following the pause is often increased in magnitude. The premature beat is a small beat, accompanied by heart-sounds feebler than those coinciding with the normal beat; the electrocardiographic appearances are characteristic (Figs. 534–537).

B. **Intermission** of a beat or beats may be due to one of three causes: a premature extrasystolic beat too feeble to reach the wrist; a blocked auricular stimulus; or a comparative failure in the contractility of the ventricle.

1. If the intermission is due to a feeble extrasystole, the imperfect heart-sounds which accompany the premature beat will be audible. A sphygmographic tracing will sometimes bring to light a wave too feeble to be perceived by the finger. The pause due to the intermission is shorter than the duration of two complete beats, if the gap is due to an unperceived extrasystole which is not followed by a compensatory pause.

2. If due to a blocked auricular impulse, this can only be proved by demonstrating the occurrence of auricular systole without a corresponding ventricular systole following at the usual interval; and it is scarcely possible to do this without a polygraph record of jugular and radial pulses, or an electrocardiogram. The auricular systole may be audible, and its effect visible in the jugular vein; but in both cases timing by clinical observation alone is a difficult matter.

3. If it is due to a normally-timed ventricular systole too feeble to send a wave to the wrist, other evidences of failing contractile power, among them the alternating pulse, are sure to be detected; indeed, this type of intermission is in reality an exaggeration of the alternating pulse, without which it will not occur.

C. —**Short Periods of Irregularity** due to a 'sinus disturbance' are very common, especially in children and nervous subjects. The diagnostic features are absence of physical signs of cardiac disease, marked variation in rhythm with respiration and swallowing, and implication of the whole heart auricle as well as ventricle in the irregularity. This latter fact is of course only discerned by means of graphic records; but the diagnosis can usually be made without recourse to these.

Longer periods of total arrhythmia (see below, IV, A) sometimes interrupt a normal rhythm. These may occur in persons with no signs of organic heart disease, whereas continuous total arrhythmia is always a sign of serious structural change.

III. —*The radial pulse is arranged in pairs of beats.*

Fig. 539. —Pulsus bisferiens. There is a double peak to each radial beat, simulating a pair of beats.

A. **The Pulsus Bisferiens**

is a single beat with a double summit (Fig. 539). This can be recognized easily by the fact that the two summits are very close together, and that one cycle only of heart-sounds corresponds to each pair.

B. Alternating Extrasystoles cause the pulse to be paired (*pulsus bigeminus*): each pair consists of a full beat, followed after an abnormally short pause by a small beat. Each beat, whether normal or abortive, is accompanied by a cycle of heart-sounds; though the second sound may fail if the accompanying premature extrasystolic beat is too feeble to open the aortic valves. A polygraphic or electrographic record (*Fig. 534*) will help to make the nature of this irregularity clear.

C. The Pulsus Alternans is associated with other evidences of inadequate contractile power. Each beat consists of a full beat and a small beat, and each beat is equidistant in time from that preceding and that following (see *Fig. 533*). A similar alternation in cardiac force may be detected in the heart-sounds. In many cases the alternation can only be recognized with certainty by means of a sphygmomanometer (see p. 674).

D. Blocking of Every Third Auricular Stimulus results in the ventricular contractions being arranged in pairs. Each beat is of equal force, and the interval separating each pair from that following it is equivalent to the duration of two normal pulse waves.

Beats may fall regularly in groups of three or four if every fourth or fifth beat is either an extrasystole, or missing by reason of auriculo-ventricular block.

IV. *The pulse is totally irregular, no fundamental rhythm being discoverable.*

A. True Total Irregularity is associated with organic disease, either post-rheumatic or cardiosclerotic. The pulse and heart-sounds are altogether irregular, and the circulation is obviously embarrassed. The picture is therefore characteristic: if any doubt is present, discovery of evidences of auricular asystole (loss of presystolic thrill and murmur, failure of the auriculo-systolic wave in the jugular curve of a polygraph tracing (*Fig. 526*), and disappearance of the auricular complex from the electrocardiogram with presence of characteristic quick irregular auriculo-fibrillational movements (*Fig. 527*) will remove it.

B. Total Irregularity may be Simulated by extreme sinus irregularity, by depression of conductivity leading to variations in the *a c* interval (*Fig. 524*), and also by multiple extrasystoles. In such cases all that is needed to establish a diagnosis is a polygraph tracing or an electrocardiogram.

It is clear from this brief summary that many forms of arrhythmia can be recognized without the use of special apparatus: in many instances a polygram or an electrocardiogram assists greatly in making certain of the nature of the irregularity, while in a few cases nothing but an electrocardiogram will suffice to demonstrate the meaning of an arrhythmia.

Carey Coombs.

PULSE, UNDULY RAPID. (See TACHYCARDIA, p. 856.)

PULSE, UNDULY SLOW. (See BRADYCARDIA, p. 107.)

PULSES, UNEQUAL. Inequality of the pulses may be a perfectly natural phenomenon: one frequently finds that the radial arteries of the two sides are not of the same calibre, owing to variable degrees of collateral circulation by an enlarged *comes nervi mediani*. Inequality of the pulses is a much more important sign when known to have developed in a patient whose pulses were formerly normal. In such a case the cause is probably one of the following:

Thoracic aneurysm	Accessory cervical rib	Atheroma.
Mediastinal new growth	Embolism	

Pathological inequality of the pulses, or definite delay of one behind the other, as gauged by simultaneous palpation of the two radial pulses, is distinctly uncommon, even in cases of thoracic aneurysm: it is true that when very careful simultaneous sphygmographic records are made from the two radial pulses slight differences in size and definite differences in time can be detected, the one being delayed behind the other: but in clinical medicine such minute methods of investigation are seldom applicable: if the aneurysm involves the origin of the innominate artery, the right pulse will be smaller than the left: if it affects that part of the arch from which the left subclavian artery is derived, the left radial pulse will be smaller than and delayed behind the right. Similar delay or inequality might be produced by *new growth* compressing either the innominate artery on the right side or the subclavian artery on either side.

An *accessory cervical rib* might kink the subclavian artery, but the condition is generally bilateral, so that it rarely produces inequality of the radial pulses; its symptoms are more likely to be those of interference with the lower part of the brachial plexus, with consequent pain, paræsthesia, or paresis corresponding to the nerves distributed upon the ulnar aspect of the arms and hands (p. 544).

Embolism of one or other radial artery will rather obliterate it altogether than cause it to be less in size than that of the other side; the cause is almost always fungating endocarditis (p. 45).

Atheroma of the brachial or subclavian artery on one side might cause the corresponding radial pulse to be less than that on the other; but it is probable that atheroma of the aorta with an aneurysmal dilatation would be diagnosed rather than atheroma restricted to the vessels in the upper arm, unless the X rays exhibited no trace of aneurysmal opacity in the thorax.

Herbert French.

PUPIL, ABNORMALITIES OF THE. Abnormalities of the pupil may be classified into: (I) *Irregularities in shape*; (II) *Irregularities in movement and size*.

I. Irregularities in Shape.—The normal pupil is circular, or slightly oval with the longer axis horizontal. Its outline may become irregular owing to an adhesion between the iris and the lens, the result of *old iritis*; these adhesions are most evident when the pupil is dilated. A similar irregularity sometimes occurs with the *persistence of a pupillary membrane*—a congenital affection; the adhesions due to this cause are distinguished from inflammatory adhesions by the fact that they arise from the anterior surface of the iris at a slight distance from the pupil, and not from the posterior surface and the extreme edge.

The pupil may also become irregular in shape as the result of *injuries*, such as rupture of the sphincter, and tearing of the root of the iris from its ciliary adhesion (iridodialysis); of dislocation of the lens; or of partial adherence to an old perforated corneal ulcer.

II. Irregularities in Movement and Size. Before considering the irregularities in the movements and size of the pupil it is desirable to remember that its normal size varies during life. In extreme infancy it is small. It becomes larger during young adult and middle life, and ultimately becomes small again in old age. It is also, as a general rule, small in hypermetropic, and large in myopic eyes.

There are also four normal pupillary reflexes: (i) The light reflex; (ii) The reflex to accommodation; (iii) The reflex to sensory stimulation; (iv) Psychic reflexes. The reflexes to light and to accommodation are both constrictive, the constriction in accommodation being more in the nature of an associated muscular action. The sensory and psychic reflexes are both dilatations, the dilatation being caused by either sudden sensory stimuli or some sudden emotion such as fright or terror.

The pathological variations in the pupil may be classified as follows:

1. *Loss of the Pupillary Light Reflex*, either with or without constriction of the pupil, but with persistence of the reaction to accommodation, constitutes the Argyll Robertson pupil. It never occurs in healthy individuals, and is observed most frequently in *tuberculosis*, to an extent varying according to different observers from 70 to 90 per cent of all the cases. The condition is usually permanent. It also occurs in *general paralysis of the insane*. The pupil is constricted in nearly all tabetic cases, and the affection is most commonly bilateral.

2. *Loss of Convergent Accommodation Reflex and Retention of the Light Reflex*. This condition is extremely rare, but has been observed in *diabetes mellitus*, *syphilis*, *basal meningitis*, *myelitis*, and *tumour of the corpora quadrigemina*.

3. *Loss of the Convergent Pupillary Reflex* may be unilateral or bilateral. It occurs, rarely, in *tuberculosis*, and after some cases of *diphtheria* and *alcoholic intoxication*.

4. *Loss of all Reflex Movements of the Pupil*. In this condition there is paralysis of the sphincter of the pupil and of the ciliary muscle, the extrinsic eye muscles being unaffected (ophthalmoplegia interna). The site of the lesion must be in the third-nerve nucleus, and it is most frequently unilateral, though occasionally bilateral. *Syphilis* is the most frequent cause. It may also occur after *diphtheria*, *injury*, or in some intracranial diseases.

5. In the condition in which there is a lesion of the optic nerve on one side, between the chiasma and the globe, there will be, as a result, a loss of direct light reflex in that eye, and of the consensual light reflex in the opposite eye.

6. *Loss of Sensory or Psychic Reflex* occurs in lesions of the dilator pupillary tract, such as *paralysis of the cervical sympathetic*: in which condition it is associated with slight ptosis of the upper lid, enophthalmos, and diminished tension of the globe.

7. *Abnormal Constriction of a Pupil, with Retention of the Light and Convergent Reflexes*, may occur from abnormal stimuli of the sphincter, or paralysis of the dilator pupillæ as the result of acute *encephalitis*, *intracranial abscess*, or *growth* in which the lesion irritates but does not destroy the centre for convergence. In all cases of brain disease the constriction is ultimately replaced by dilatation.

8. *Abnormal Dilatation of the Pupil, with Retention of the Light and Convergent Reflexes*, is met with in cases of stimulation of the cervical sympathetic, for instance by an aortic *aneurysm*, or by a *mediastinal sarcoma* or *lymphosarcoma* or *lymphadenoma*, or by a *pulmonary carcinoma*, in the early stages when the growth has not destroyed and therefore paralysed the nerve. The diagnosis will be afforded by X-ray examination of the chest (Fig. 214, p. 249; Fig. 105, p. 114, etc.). It may also be observed in certain mental states, such as *epilepsy*, *acute mania*, or *cataplexy*.

9. *Inequality in the Size of the Pupils* is observed frequently, and may have no pathological significance: but pronounced difference in the size of the pupils may be symptomatic of some organic lesion. In cases where the abnormal pupil is the smaller, the condition is usually due to hyperæmia of the iris, such as occurs in *iritis*: *paralysis of the cervical sympathetic*: or the use of a myotic drug such as *physostigmine*. In cases where the abnormal pupil is the larger, the dilatation is usually due to *stimulation of the sympathetic*, the use of a mydriatic such as *belladonna*, *atropine*, or *homatropine*, *paralysis of the fibres of the third nerve*, or increased ocular tension, such as may occur in *glaucoma*.

In cases of inequality of the pupils one may suspect *tubercles*, general paralysis of the insane, a unilateral lesion of the third nerve or cervical sympathetic, trigeminal neuralgia, carotid or aortic aneurysm, a unilateral intracranial lesion, or *glaucoma*.

One needs to beware of the *glass eye*: if one does not make sure that both eyes are the patient's own it is possible to suspect disease when really the unequal pupils result from one of them being in a false eye.

10. Irregularities in the shape of the pupils other than those mentioned above may occur in *tubercles* and various cases of *insanity*. There is no marked or sharp irregularity, it only being noticed that the pupil is not circular owing to paralysis of certain fibres of the iris: one or both pupils may be oval, and one or other or both may be excentric, that is to say, not in the centre of the front of the eye.

11. *Hippus*. This term is applied to a condition in which, when both eyes are shaded, and then illuminated, the pupils alternately dilate and contract. It is sometimes associated with nystagmus, and occurs also in *disseminated sclerosis*, and in some cases of *brain tumour*. It is observed most frequently when there is a central scotoma in the field of vision, with some injury to the macular or axial fibres of the optic nerve. It is also common in *alcoholic subjects*.

12. *Paradoxical Pupillary Reflex*: pupils dilating under the stimulus of light. This condition is extremely rare, and has only been observed in patients affected with grave lesions of the central nervous system, usually *tubercles dorsalis*.

13. *Hemianopic Pupillary Reflex*: lesions of the brain situated in the optic tract above the corpora quadrigemina may give rise to partial loss of vision, but will not affect the pupil-reflex arc. For example, a lesion in the right occipital cortex may give rise to a left homonymous hemianopsia, but the pupil will react even when a light is thrown on the blind side of the retina (see HEMIANSOPIA, p. 377). In cases, however, where the lesion is situated in the optic tract below the corpora quadrigemina, hemianopsia may also occur, but under these circumstances no pupillary reflex for light can be obtained on stimulus of the blind side of the retina, the pupil reacting to light when the opposite side of the retina is stimulated. This reaction is termed the hemiopic pupillary reflex and is of value in the localization of intracranial lesions.

Herbert L. Eason.

PURPURA signifies hemorrhage into the skin, and, according to the size of the extravasation of blood the lesions are spoken of as *puncta* or *spots*, *vibices* or *lines*, *petechiæ* or *small patches*, *ecchymoses* or *bruises*. The lesions cannot be obliterated by pressure with the finger, which distinguishes the effused blood from mere congestion.

The diagnosis of the actual fact of purpura is seldom difficult : the persistence of the discoloration under pressure differentiates it from erythematous lesions, and the colour generally serves to distinguish it from pigmentation of the skin other than that due to hæmorrhage. In a case of doubt the fact that the lesions presently alter in colour and then disappear serves to distinguish purpura from capillary nævi or from pigmentation of the skin, which persist. It may be more difficult, however, to decide what is the nature of the purpura in any given case : the following is a list of its better-recognized causes :

CAUSES OF PURPURA.

1. **Due to Local Injuries :**

Flea-bite Pediculosis Bug-bite Leech-bite	Blows Sprains Rupture of a muscle	Rupture of a vein, especially a varicose vein Punctures by hypodermic needles.
--	---	---
2. **The Effect of Drugs and Poisons :**

Antipyrin Iodoform Iodide of potassium Sulphonal Copaiba Belladonna Chloral	Chloral hydrate Butyl-chloral hydrate Veronal Mercury Arsenic Quinine Ergot	Salicylic acid Potassium chlorate Diphtheritic antitoxin Ptomaine Snake-bite poison.
---	---	--
3. **In Fevers :**

Typhus fever Cerebrospinal fever Small-pox Pyæmia Septicæmia Fungating endocar- ditis General tuberculosis Dysentery	Cholera Yellow fever Weil's disease, bilious typhoid, spirochaetosis icterohæmor- rhagica Plague Remittent fever Severe malarial fever Blackwater fever	Measles Diphtheria Typhoid fever Scarlet fever Rocky Mountain spotted fever Tsutsugamushi, or Kedam disease of Japan.
--	---	---
- 4.— **In association with Jaundice from whatever cause** (see JAUNDICE, p. 405).
5. **Bright's Disease.**
- 6.— **Chronic Alcoholism :**
Cirrhosis of the liver | Peripheral neuritis.
7. **The so-called Blood Diseases :—**

Splénomédullary leu- kæmia Lymphatic leukæmia Lymphadenoma	Pernicious anæmia Splenic anæmia Pseudo-leukæmia infantum Scurvy	Barlow's disease Hæmophilia Aplastic anæmia Aplastic myelæmia.
---	---	---
8. **In cases of generalized Malignant Disease, especially :—**
Sarcomatosis | Chloroma.
9. **Peliosis Rheumatica.**
10. **Henoch's Purpura.**
11. **Purpura Simplex :—**
Morbus maculosus of
Werlhof | Purpura hæmorrhagica | Purpura fulminans.

A number of the above conditions require but little discussion, for if they are only borne in mind their diagnosis will generally be easy.

1. **Due to Local Injuries.**—*Flea-bites* are by far the commonest cause of purpura in the out-patient department of a hospital, and they may sometimes be so numerous as to raise a misleading suspicion that the patient is suffering from some serious disease. The relatively small hæmorrhagic foci, and their prevalence on the parts covered by the clothes

rather than upon the hands, face, or exposed parts of the legs, serve to indicate the diagnosis: even in a severe case examination of the purpuric spots under a magnifying glass reveals the central puncture of the bite.

The commonest variety of *pediculus* to produce purpura is *P. corporis* or *vestimentorum*: the circumstances of the case and the distribution of the purpura itself and of the marks of scratching, particularly in the regions where collars and other constrictions in the dress occur, would indicate the diagnosis.

Bug-bites will be suggested by the circumstances of the case and the central puncture: in susceptible individuals the purpuric areas may be as large as threepenny bits, or larger, and they are often purplish or bluish rather than bright red.

The hemorrhage around a *leech-bite* is so characteristic that, once seen, it cannot be mistaken for anything else.

Bloes and *sprains*, if sufficiently severe, produce purpura even in the healthy, in whom the history gives the diagnosis: some normal individuals bruise with such ease that there may be no clear evidence of injury unless careful inquiry is made, when some trivial stumble or knock may be recalled to mind by the patient. Such easy bruising may also occur in any of the blood diseases. A case of *epilepsy* may sometimes come under observation for multiple bruises simulating some other kind of purpura, but due to injuries produced during the attacks which may themselves be unsuspected if they occur during the night. Very extensive purpura on the legs or other parts has sometimes been produced by multiple self-injury in girls suffering from *hysteria* or by *malingers*: serious organic disease may be feared unless other factors in the case or the distribution of the purpura suggests an artificial origin: the hemorrhagic spots and blotches may be abundant on the fronts and sides of the legs, for instance, and not down the backs of them: organic purpura seldom has so selective a distribution.

Spontaneous *rupture of a muscle* leads to extensive purpuric extravasation of blood, but the diagnosis is not difficult if the history is clear: one can often feel the place where the muscle has given way unless it is too deep-seated to palpate, as in the case of the plantaris longus, which is apt to rupture during sudden efforts such as may be made in playing tennis or the organ.

The *purpuric discoloration of the skin around varicose veins* in the legs, together with its resultant dark-brown pigmentation, is familiar to all.

2. Drugs and Poisons.—As regards *drugs*, the list above indicates that there are many which may sometimes produce purpura: it may be said at once, however, that none do so at all commonly. Nevertheless the possibility should be borne in mind, and inquiry made as to the remedies the patient may have been taking. *Antidiphtheritic serum* and *ptomaines* merit particular attention. The commonest eruption resulting from antidiphtheritic serum, or from other forms of antitoxic horse-serum administered hypodermically, is urticaria: purpura is relatively rare: either form occurs as a rule about nine or ten days after the serum has been given, and is generally associated with lassitude, muscular and joint pains, anorexia, and more or less pyrexia, lasting from a few hours to two or three days. Ptomaine poisoning is often difficult to recognize with certainty unless it occurs in epidemic form. It is due in most cases to the products of Gaertner's bacillus, and seeing that the blood-serum of patients affected by this bacterium develops agglutinating powers against it similar to Widal's reaction for typhoid fever, this serum test should not be omitted: if it proves positive the diagnosis is clear: a negative result, however, does not exclude ptomaine poisoning.

3. Due to Fever. In the majority of *acute fevers* the occurrence of purpura is of prognostic rather than of diagnostic value: in diphtheria, for example, even a single well-defined purpuric spot is a sign of grave omen, but it does not assist at all in the diagnosis of the disease, which has to be recognized upon other grounds. The two fevers in which purpura is of essentially diagnostic value are *typhus* and *cerebrospinal fever*. The former is now very rare in Great Britain, but when it was common and typhoid fever began to be differentiated from it, the point upon which greatest stress was laid was that in true typhus or gaol fever there is always more or less purpura, whereas in typhoid fever all the red spots fade upon pressure. It happens occasionally even yet that typhus fever develops in the poorest parts of cities, and this point is most useful in distinguishing it from typhoid. In the latter, if flea-bites are excluded, purpuric spots are exceedingly rare. Cerebrospinal

fever presents many characters that are common to it and to other forms of acute meningitis; but if with these there is a purpuric eruption it is differentiated from the others, though the absence of purpura does not exclude the disease. So characteristic is the purpura in some cases that the malady has earned the title of spotted fever, which used to occur in widespread epidemics, and still does in smaller ones from time to time. The diagnosis may be clinched by bacteriological examination of the cerebrospinal fluid obtained by lumbar puncture.

Small-pox may present cutaneous hemorrhages of three different kinds: there may be hemorrhage *into the pustules* in a late stage, when the diagnosis has already been made and when the prognosis is not thereby made worse; there may be hemorrhage *between the pustules*, vesicles, or papules, in which case the prognosis is not good; and there may be a hemorrhagic eruption either all over the body or in the bathing-drawers region in the *prodromal* stage of the disease, in which case the patient will almost certainly die before the true small-pox eruption develops, so that if there is not an epidemic at the time the diagnosis may be difficult.

Almost any condition in which there are pyogenic micro-organisms or their toxins circulating in the blood-stream may be associated with extensive purpura, and this applies

Fig. 549. From a photograph showing extensive purpura in a case of fungating endocarditis. The limbs were affected more than the trunk. From the same case as Fig. 545, p. 787.

to *pyæmia* and *septicæmia* in general. The diagnosis will be confirmed best by obtaining cultivations from the blood, though should blood-cultures prove negative septicæmia will not be excluded necessarily: there will very likely have been rigors, pyrexia, and other symptoms pointing to the nature of the case. *Fungating endocarditis* is a variety of pyæmia or septicæmia. Seeing that it is very rare to get purpura in association with chronic valvular disease of the heart if both purpura rheumatica and infective endocarditis can be excluded, the occurrence of purpura in a heart case (Fig. 540) may be one of the main symptoms indicating that fungating endocarditis has supervened. So

definite is the nomenclature in regard to this disease, that the terms malignant, ulcerating, fungating, infected, and infective endocarditis are used indiscriminately by different observers to denote the same condition. The purpura may be general or local: the former when there is hæmolysis, the latter after a splutter of minute peripheral emboli; occasionally the purpura is confined to a single linear hæmorrhage in the long axis of a nail—a rarity, but none the less a thing which may be the first signal of the dangers of the case. The disease may be further indicated by symptoms described on p. 45. *Pyorrhæa alveolaris* is another septic infection which leads occasionally to extensive purpura and other hæmorrhages, and sometimes the patient develops purpura of obscure origin when the real cause lies in *infected tonsils*, especially when these are the persistent habitat of the *Streptococcus hæmolyticus*.

General tuberculosis is not a common cause of purpura, and yet in a few instances extensive purpura has been the first, and for the time being the only, symptom of an obscure illness which has ultimately turned out to be general tuberculosis. The patient has generally been a child, and the diagnosis has only been possible when the course of the case has been watched. The same may be said of *sarcomatosis* in certain cases, though this has been included under a different heading in the above list.

The remainder of the fevers mentioned above are diagnosed, not from the purpura,

but from the other symptoms, from the general circumstances, and from the geographical incidence of each. *Rocky Mountain spotted fever* is due to infection from the bites of ticks (*Dermacentor venustus*, Fig. 479, p. 625), a similar disease being met with in the Himalaya mountains and probably in other regions, but not in England; *kedani disease* is seen in Japan, where it is caused by a mite analogous to the harvest-mite of England. The illness has a high mortality, is associated with pyrexia lasting an average of about two weeks, and is characterized by the development of multiple small hemorrhages appearing on the face at the end of the first week, spreading thence to the trunk, and sometimes to the extremities—a generalized purpura.

4. **Jaundice.**—This should be borne in mind as a cause of purpura, for although the occurrence of the latter does not assist in differentiating one kind of jaundice from another, one might be misled into diagnosing something more serious than is necessary if one did not bear in mind that any kind of jaundice may produce purpura. Moreover, some of these patients might seem to have been grossly ill-treated if one were to judge only by the degree of bruising that may result from ordinary palpation: the danger of fatal oozing after operation is always to be remembered when surgical measures are thought of in a jaundiced subject. Spontaneous hemorrhage into the skin is less common here than is hemorrhage from what otherwise would be trivial causes.

5. **Bright's Disease,** particularly the chronic varieties, may produce hemorrhage anywhere in the body. Purpura is not a very common form of such hemorrhage, but when it does occur it may be extensive. The diagnosis is discussed under ALBUMINURIA (p. 9).

6. **Chronic Alcoholism,** especially if it has already lead to either cirrhosis of the liver or peripheral neuritis, is occasionally a cause of considerable purpura, though the latter is generally confined to the legs, particularly to the parts below the knees. In many instances the diagnosis is easy, even if the history is not given with perfect honesty: but considerable difficulty sometimes arises in the case of ladies who have contracted the habit of secret drinking, their relatives and friends being entirely unaware of it.

7. **Blood Diseases.** Any of the so-called blood diseases may present purpura as a prominent symptom, and in some cases, particularly in *lymphatic leukaemia* in children, extensive purpura may be the first symptom that anything is wrong. More often, however, the disease has already given rise to anemia or to enlargement of the spleen or lymphatic glands, or to some other prominent hemorrhage, and the diagnosis has already been made by the time the purpura supervenes. (See ANEMIA, p. 25; LYMPHATIC GLAND ENLARGEMENT, p. 471; and SPLEEN, ENLARGEMENT OF THE, p. 774.)

Scurvy in an adult is relatively rare, but is sometimes met with in those who have been obliged by poverty to live upon a diet containing no fresh vegetables, in which case typical scurvy may develop, with the spongy heaping up of the gums both inside and outside the teeth, and with the knotty hemorrhagic swellings in the muscles of the calves, as well as purpura. Children who are fed upon patent foods without sufficient fresh milk or vegetable food or fresh meat not infrequently develop a milder form of scurvy, with marked tenderness of the periosteum of the long bones, pasty pallor, mouth bleeding from spongy gums, and possibly purpura: this is *infantile scurvy*, or *Barlow's disease*, which should not be confused, as it is apt to be, with rickets, though it has been called scurvy rickets sometimes.

Hæmophilia is generally indicated at once by the history of persistent oozing from slight cuts and scratches, and also by the fact that other members of the family, especially males, have suffered in a similar way: it is commoner to get gross subcutaneous, sub-mucous, intramuscular, or intra-articular hemorrhage in this disease than for it to produce generalized purpura.

8. **Generalized Malignant Disease.**—*Chloroma* is a very rare disease, in some ways related to sarcomatosis, and in others to lymphatic leukaemia: it produces swellings in connection with the bones, especially of the head, together with enlargement of the lymphatic, lachrymal, and salivary glands: it develops in early life, proves slowly fatal, and the diagnosis is confirmed by the green colour of the new-formed tissue—'green cancer'. The blood changes are negative.

9. **Peliosis Rheumatica, purpura rheumatica, or Schönlein's disease,** was formerly regarded as related to acute rheumatism: but it is rare for a patient affected by it to present unmistakable valvular heart disease, though there may be a local systolic bruit at the

impulse. In addition to the extensive purpura, which comes out in successive crops and may affect any part of the body, though it is commoner upon the lower limbs than elsewhere, there is considerable pain, redness, and swelling of many joints, which may become affected successively; the temperature rises during an attack to 103° or 104°, the throat generally being sore at the same time. It is not impossible that the purpura is due to the absorption of microbes or their toxins from the acute tonsillitis; the diagnosis is not difficult when the purpura, the joint pains, and the pyrexia are present together. The disease is little influenced by sodium salicylate; it may be associated with more or less erythema as well as purpura; the malady affects young persons, especially between the ages of ten and thirty, of either sex.

10. Henoch's Purpura is met with chiefly in children (*Fig. 337*, p. 428), and the patient may suffer from recurrent attacks, which usually cease at or before puberty. In addition to hemorrhages beneath the skin there is generally some tendency to joint pains not unlike those of peliosis rheumatica, but in addition to this the child is seized with more or less severe acute abdominal symptoms, varying from simple vomiting and stomach-ache to severe prostration with agonizing cramp-like attacks of colic, some of which may be followed by the passage of blood and mucus per rectum to such an extent as to simulate acute intussusception; the abdominal attacks are probably the result of submucous intestinal hemorrhages. There is every degree of the affection, from mild to very severe, but the association of the purpura with the abdominal attacks in childhood suggests the diagnosis at once, especially if there has been a similar attack previously. The chief error to avoid is mistaking for Henoch's purpura that which is really an acute nephritis; the urine should be examined periodically for albumin and renal tube-casts, even if there is no oedema, though the occurrence of blood alone would not be sufficient to indicate acute nephritis, seeing that hemorrhage from the kidney may be due to Henoch's purpura itself.

11. Purpura Simplex.—It is only when every precaution has been taken to exclude all the above causes of purpura that one can be satisfied with any of the remaining three diagnoses, namely, *purpura simplex* (*morbis maculosus* of Werlhof), *purpura hemorrhagica*, or *purpura fulminans*. These differ from each other only in degree; broadly speaking, *purpura simplex* signifies hemorrhage into the skin only; *purpura hemorrhagica* has, in addition, hemorrhages from the mucous membranes, particularly of the mouth, nose, and bowel, less commonly of the urinary passages; whilst *purpura fulminans* is the term used to denote a condition in which a person may seem perfectly healthy to-day, may be seized with acute purpura and be dead before to-morrow, without developing any other symptoms to indicate the nature of the complaint. These kinds of purpura have sometimes been spoken of as idiopathic, but they must have some underlying cause if only it can be found. It is better probably to label them cases of purpura of which the exact cause is not yet known than to be content with such a term as *purpura simplex*, and it is probable that if bacteriological examinations were made, a bacterial cause would be uncovered, particularly in connection with the tonsils, the gums in states of septic gingivitis or pyorrhoea alveolaris, the uterus, the bowel, or the circulating blood itself.

Herbert French.

PUS IN THE CHEST. (See CHEST, PUS IN, p. 132.)

PUS IN THE STOOLS in sufficient amount to be recognizable by the naked eye indicates the rupture of an abscess into the intestinal tract. The symptom is rare, however, for even when a large appendicular abscess perforates into the caecum the pus either becomes indistinguishable when mixed with the faeces, or unrecognizable on account of digestion and decomposition. The less the pus is mixed with other intestinal contents, the nearer to the anus has the site of rupture been; but the diagnosis of the source of the abscess needs to be determined upon other grounds, particularly the history, and the results of general physical examination, including that of the rectum and vagina. Abscesses most apt to cause a discharge of pus with the stools are of the appendicular, cholecystic, perinephric, psoas, pelvic, perigastric, or other local peritoneal types, and pyosalpinx.

Microscopical quantities of pus in the stools may be due to any of the causes already mentioned; they may also be derived, not from lesions outside the intestines, but from

affections of the mucous membrane itself: acute or chronic colitis, with or without ulceration: dysentery: cholera: dengue: mucous or mucomembranous colitis: tuberculous, typhoidal, malignant, or venereal ulceration of the bowel. The pus corpuscles may be recognizable as such under the microscope: but it is difficult to determine when the leucocytes derived from the intestinal catarrh are merely leucocytes in excess, and when their numbers become sufficient to merit the term actual pus. Examination with the sigmoidoscope is sometimes invaluable when the diagnosis has not been decided by other methods.

Herbert French.

PUSS IN THE URINE. (See PYURIA, p. 715.)

PUSTULES. The pustule, one of the primary cutaneous lesions, is an epidermic elevation, either unilocular or multilocular, containing a purulent liquid, and differing from a vesicle or a bulla only in the character of its contents. Always a product of inflammation, it may originate as a pustule or may develop from a papule, but much more often it is a transformed vesicle: if the metamorphosis is imperfect the lesion is styled a papulo-pustule or a vesico-pustule. Frequently the transformation from a papule or a vesicle is so swift that the true origin of the lesion may escape notice: but in such cases it is usual to find papules or vesicles intermingled with the pustules. The pustular cavity may be situated in the epidermis, in the derma, or in a follicle: a purulent accumulation *beneath* the derma is either an abscess or a gumma. *Epidermic* pustules may be superficial, as in impetigo, or deep, as in the condition known as ecthyma, which is a severe form of impetigo. *Dermic* pustules, such as the miliary abscesses of new-born children, are seldom met with, while *follicular* pustules, such as those of sycosis, are common. In *colour*, pustules are usually yellowish or greyish, with a red areola: but when the contents are mixed with blood, the yellow may be tinged with red or brown. If a pustule is punctured or ruptured, the liquid is seen to be more or less turbid and yellowish: under the microscope it is found to consist largely of leucocytes and serum as well as cocci. Pustules vary greatly in size: small ones may remain of inconsiderable dimensions, or may become large by excentric extension. The prevalent *shape* is roundish or convex, as in furuncle and aene: but it may be acuminated, as is frequent in sycosis and eczema, or flat and irregular, as in impetigo and syphilis, while in rare instances, as sometimes in scabies, it may be oblong, with a tendency to a linear form. In variola and the varioliform syphilide, the pustules may be flattened or concave, either because the fluid may not fully distend the cleft in which it lies, or from flaccidity of the sac due to commencing absorption. Pustules may develop slowly, as sometimes occurs in impetigo and in the pustular syphiloderma: but as a rule they run a rapid course, and terminate either by rupture, much more often accidental than spontaneous, or by desiccation. In either case, a yellow, brown, or blackish crust, more or less thick and irregular, is formed: but if the termination is by desiccation, the crust has a less pronounced coloration, and is friable instead of firm.

A cutaneous affection in which the pustule plays a leading part is *impetigo vulgaris seu contagiosa*: usually following slight febrile disturbance, small erythematous spots appear, on which form vesicles containing a turbid fluid that quickly becomes purulent: when the pustules break, as they soon do, they discharge a fluid that dries up quickly into scabs that are at first yellowish, and afterwards green. Dotted about among the scabs are pustules, which may coalesce so as to form, on rupture, crusts of considerable size. The eruption may be limited to a few discrete lesions, or may extend over large areas of the body. In parts where the pustules are exposed to friction, as on the limbs, they are generally ruptured at an early stage, and a flat irregular scab, surrounded by an areola, forms over them: the condition known as ecthyma. Sometimes the distribution is annular (*impetigo circinata* or *gyrata*). In the condition known as *impetigo bullosa* the lesions are much larger, and are not always transformed into true pustules. With impetiginous eruptions, though not with these alone, *cutaneous diphtheria* is sometimes associated, especially in children. The most typical form of this affection has the appearance of an impetiginous eczema, associated with conjunctivitis, and occasionally with otorrhoea and rhinitis. No diphtheritic membrane may be present, and, if cutaneous diphtheria is suspected, the Klebs-Löffler bacillus should be sought for bacteriologically.

Streptococci and staphylococci are the organisms generally found in simple impetigo, but occasionally other organisms may be associated with them. The *Bacillus coli communis* for example, the *Bacillus pyocyaneus*, or the *Bacillus mallei* in those whose occupation amongst horses may have rendered them liable to be infected by glanders.

The differences between impetigo vulgaris and *follicular impetigo* are well marked. The latter is pustular from the beginning, and always situated around a hair-follicle. It starts as a round pustule, often pierced by a long or coarse hair, and it may be quite small, or as large as a pea: the pus collects under the horny layer, which it distends and raises. The eruption, usually multiple, has no sites of election, but appears wherever a breach in the horny layer affords entrance to the pyogenic organism. The pustules are more resistant than those of impetigo contagiosa, and are less liable to break. When they rupture, yellow crusts, smaller and thinner than those of impetigo vulgaris, are formed. The pustules of follicular impetigo can hardly be mistaken for those of any other affection. The common form of impetigo, however, has in rare cases to be diagnosed from pemphigus. In the latter the lesions start, not as small vesicles but as bullæ, and the fluid they contain is only sometimes inoculable. Usually, too, there is marked systemic disturbance. But it is with *pustular eczema* that impetigo vulgaris is most likely to be confused, especially when the pustules of the latter condition have run together into a patch. In eczema, however, the pustules are smaller, there are severe itching and burning, there is an inflammatory areola around the crusts, which is seldom the case in impetigo vulgaris, and other definitely eczematous lesions will usually be found if sought for carefully, including infiltration and thickening of the integument.

Like follicular impetigo, *sycosis vulgaris* is a staphylococcal infection. The lesions begin as papules, or as nodules which form round the hairs—usually of the face, and especially of the chin, but sometimes attacking the eyebrows, eyelashes, and the axillary and pubic regions—and presently develop into pustules, each of them pierced by a hair. As the result of suppuration, the hairs are loosened, and if one is pulled out, a drop or two of pus usually exudes. In severe cases the pustules may be packed so closely together as to form infiltrations, which may fungate. The chief diagnostic features of the affection are its inflammatory character, its origin in the hair-follicles, and its limitation to the hairy parts, usually of the face. The differential diagnosis from tinea sycosis has been given under FUNGUS AFFECTIONS OF THE SKIN (p. 309). Eczema is not limited to the hairy parts, and if the follicles are involved it is only secondarily, nor, as a rule, is the inflammation so severe as in sycosis vulgaris. Of sycosis vulgaris, again, intense itching is not a feature. Sometimes, when the sycosis is widely diffused, the crusts may have to be removed to clear up the diagnosis: when this is done, the follicular implication will soon be perceived. Tertiary syphilitic ulceration is deeper and is not restricted to the follicles, and behind it there lies a history of earlier specific lesions, as well as of the primary infection, unless this should have escaped notice. Wassermann's serum test may be applied.

If there is any doubt as between sycosis vulgaris and acne vulgaris, the presence of the latter on non-hairy parts should of itself suffice to decide the question. The pustules of *acne vulgaris* can scarcely, indeed, be confounded with those of any other affection, except with the lesions of small-pox (see below) and those of bromide and iodide eruptions. In these drug eruptions, however, comedones ('blackheads') are absent, the lesions occur on any part of the body, and are generally a brighter red, while the fluid they contain is rather thinner. Drug eruptions, again, occur at any time of life, whereas acne vulgaris is essentially a disease of puberty. Pustular syphilides may attack any part of the body, and are generally grouped, which is never the case with the pustules of acne.

A *furuncle* is so characteristic that the only lesion from which it can ever require to be differentiated is a *carbuncle*. The pathological process is the same in both: but while in furuncle there is but one point of suppuration and opening, in carbuncle there are several. The only condition from which a carbuncle has in turn to be diagnosed, except a furuncle and malignant pustule, is diffuse cellulitis, in which there is no circumscribed outline.

In *malignant pustule* (anthrax), following itching and burning at the site of inoculation, a livid red papule appears, on which a bulla or pustule forms quickly and breaks,

drying up into a black gangrenous eschar. This is fringed with tiny vesicles or pustules, and surrounded by a broad areola of solid oedematous infiltration, the skin over which is tense and violaceous. There are constitutional symptoms, with septic fever. The diagnosis rests mainly upon the presence of a gangrenous patch surrounded by infiltration in a patient whose occupation exposes him to infection with the anthrax bacillus, especially from cattle, hides, or wool. The organism may be detected without difficulty under the microscope. It is a relatively large bacillus which generally forms long chains and is Gram-positive. It is only at the outset that the lesion can be mistaken for a carbuncle. The primary lesion of syphilis can be excluded by its indolence, the absence of gangrene and of febrile symptoms, and by the presence of the *Spirochæta pallida*.

In *glanders*, the cutaneous lesions begin as red spots, which pass through the papular and vesicular or bullous stage into pustules that give rise to widespread ulceration. The condition, with its severe constitutional disturbance and, except in some chronic cases, the peculiar discharge from the nostrils, is usually easy of recognition: and in exceptional cases in which the diagnosis is in doubt, recourse should be had to the mallein injection test, or the *Bacillus mallei* may be isolated from the lesions. The patient's occupation as a veterinary attendant or horse dealer may suggest the diagnosis.

In *scrofulodermia* (tuberculides), usually an affection of childhood and adolescence, pustular lesions take the form which has been styled by Dühring the large flat pustular and the small pustular scrofuloderm. The former begins as one or more superficial indurations (nodular tuberculides) which, becoming pustular, extend peripherally and form a flat, yellowish, crusted pustule of considerable size, surrounded by a violaceous areola. Neighbouring pustules may coalesce. When the crust is removed, a granular scrofulous ulcer is seen. The small pustular scrofuloderm (papulo-necrotic tuberculide) is usually a papulo-pustule rather than a fully-developed pustule, the pus being frequently limited to the central part of the summit, while the outer part of the lesion remains hard. The crusting is sometimes a slow process, which may occupy several weeks, and when the crust drops off it leaves indelible scars not unlike those of variola. When the face and neck or the hands and forearms are affected, the condition is known as acnitis or folliculitis respectively. The diseases with which scrofulodermia are most likely to be confused are lupus and syphilis. The absence of 'apple-jelly' nodules will distinguish it from lupus, though the two conditions may co-exist. The syphilitic ulcer is met with in adults, and is usually a much more active process than scrofulodermia, nor has the lesion the undermined border which is characteristic of the latter affection. Concomitant syphilitic signs will usually be present, just as in scrofulodermia there will generally be other tuberculous symptoms: Wassermann's serum reaction should be tested.

In **Syphilis** the pustule is a much less frequent lesion than the papule (p. 601), and is generally found in association with a cachectic state of health. It appears in two different forms, the acuminate and the flat pustular syphilide, and in both the lesion may be either small or large. The *small acuminate* or miliary syphilide, not usually much larger than a pinhead, in most instances begins as a papule, and papules will generally be found intermingled with the pustules. When the crusts into which the pustules dry are detached, there may be some scarring, or the lesions may leave no trace except stains, which presently disappear.

The diagnosis of these small acuminate pustules seldom presents any difficulty; but it is not so with the *large acuminate* pustules, the aeneiform syphilides, which may be mistaken not only for acne, but also for variola and iodide eruptions. Appearing on a base which may at first be pink, and afterwards copper coloured, they may be pustular from the beginning, or may start as vesicles or as papules: they are more or less generalized, about the size of a pea, disseminated, or grouped irregularly, and while they are predominantly acuminate, some of them may be rounded. Some of the pustules may be dimpled, and occasionally the majority of them display this character. When the crusts fall off, brownish stains are seen, and there may be slight scarring, which, however, is seldom permanent. The grouping which is characteristic of these pustular syphilides, and the drying-up of the pus into scabs, are important points in differentiating them from the lesions of acne, which, further, instead of being generalized, seldom affect parts other than the face, the back of the neck, the chest, and the back between the shoulders. The comedones of acne are another distinguishing feature, the eruption is of a more sluggish

and chronic character, and there is no cachexia. The diagnosis as between pustular syphilides and variola is given below. The pustules met with in iodic eruptions are seldom either generalized or profuse.

Small flat pustular syphilides ('impetiginous syphilides') may begin as such, or may develop from macules or papules. They are discrete: but in such regions as the face and scalp may run together. The eruption is of a generalized character, with a preference for the genitals, the scalp, and the face. The crusts into which the pustules quickly dry are frequently adherent: beneath them there is superficial ulceration: occasionally they are surrounded by an areola of the characteristic raw-ham colour. When the eruption is extensive, the patient is often anæmic and cachectic. The affections from which these syphilides have to be differentiated are pustular eczema and impetigo. The ulceration which underlies the crusts in the syphilides is not found in either of those conditions, nor is itching present as in eczema. In impetigo, the pustules most frequently affect the face and hands, and are superficial: and the eruption is mild in character and of shorter duration.

The *large flat pustular syphilides* ('cethymatous syphilides') differ little from the small ones except in size, and the only lesions with which they are likely to be confused are those of severe impetigo vulgaris. The diagnosis from that condition must rest upon the slow development, the greater number of the pustules, the coppery areola and base, the accompanying cachexia, and the pigmented scars. But it should be remembered—and this applies not to pustular syphilides only, but to syphilis generally—that in most cases a sure diagnosis of syphilis can be made only when all the factors of the case are taken into account: the history, character, course, and termination of the lesions, and their reaction to salvarsan, mercury, or arsenic, and the iodides. The distinctive characters of secondary lesions generally are their symmetry, their coppery colour, the positions in which they occur, their polymorphism, and the absence of itching, together with enlarged glands, sore throat or tongue. In doubtful cases the whole cutaneous surface should be examined for characteristic marks or lesions. If the diagnosis is still uncertain, the Wassermann test should be applied.

Small-pox. Of all diseases of which the pustule is one of the manifestations, small-pox presents the greatest difficulty in diagnosis. The lesion, occasionally preceded by a roseolar rash not unlike that of scarlatina, begins as a mere fleck, of pin-head size, flush with the surface and impalpable. In the course of a few hours it swells up into a pink papule, which can be felt embedded in the skin like a small shot. In a few days, the papule undergoes vacuolation, at the same time getting bigger, and becoming grey and translucent. So the papule passes into the vesicle, which is loculated, so that if it is punctured the contained fluid is not entirely discharged. As a rule, the smaller vesicles are hemispherical, the larger flat-topped, and occasionally the crown is indented. After about twenty-four hours the contents become turbid and the covering dull and whitish, so the pustular stage is entered upon. While the lesion is undergoing this transition, the grey translucent centre is encircled at the periphery of the crown by a white or yellow ring. By the sixth day from its birth the lesion has become yellow throughout and the crown dome-shaped: the pustule thus attains maturity, and if of full size measures about three-eighths of an inch across. Even in unmodified small-pox, however, the lesions often fail to reach those dimensions. As the pustule develops, the erythematous zone, the areola, which encircled the papule and was biggest and brightest in the vesicular stage, begins to wane, and has disappeared by the time the pustule reaches maturity. This occurs about the ninth day. As the pustules dry up or burst, scabs are formed, which on separation leave dark stains, scars, and 'pits', the number and depth of the pits usually being determined by the severity of the disease. In mild attacks the pustules remain discrete, in severe cases they run together, confluent small-pox (*Figs. 541, 542*). In severe cases, hæmorrhage takes place into the skin and the interior of the pustules. The mucous membranes of the air-passages may be invaded, the extent to which they are involved being determined by their susceptibility rather than by the severity of the attack. In small-pox modified by previous vaccination the eruption may resemble that of the unmodified disease, as here described, the difference being that the lesions are less abundant and are seldom confluent.

It has been usual in the diagnosis of small-pox to lay the chief stress upon the solidity

and hardness of the papule, the umbilication of the vesicle, and the loculation of its cavity : but the distribution of the lesions is of more diagnostic value than their character, as also is it more easily observed. The parts most liable to the eruption are the face and hands : and of the two the face is more liable than the hands. Next to the hands in susceptibility come the upper limbs, then the trunk, then the lower limbs. As to the trunk, the rash is thicker behind than in front, and thickest on the shoulders. The incidence is smallest on the great flexures of the body, while the extensor surfaces of the limbs, and especially the elbow, receive a disproportionate share of the rash. The neck fares better than either the head or the shoulders : the back of it suffers more than the front. On the flank the rash is less profuse than on the adjoining parts of the chest-wall, either in front or behind. On the foot, the distribution is marked by great inconstancy. Usually the back of the foot receives more attention than the sole : between the toes, and in the folds beneath the toes, there is comparative immunity : and the parts for which the eruption shows most preference are the instep, especially the tendinous ridges and the bony eminences, the tendo Achillis, the balls of the toes, the toepads, and the heels. In the hand, the palm, and especially the hollow of it, suffers little, and the brunt of the attack is borne by the extensor surface : the rash is thickest on the back of the wrist and hand, and over the heads of the metacarpals. To these usual characters the distribution offers exceptions, some of them difficult of explanation : but they are neither so numerous nor so considerable as materially to lessen its diagnostic importance.

Fig. 541. Discrete small-pox of considerable severity, tending to become confluent on the face. The patient was vaccinated in infancy, and re-vaccinated six days before the eruption appeared. The face and limbs are affected more than the trunk, and on the limbs the eruption is centrifugally distributed. (By Dr. W. Hanna.)

Fig. 542. Confluent small pox in an unvaccinated patient. (By Dr. Norman Scott.)

prominent as the papules of small-pox, and they appear chiefly on the trunk, and clect the abdomen and chest rather than the back : the arms and legs, and especially the face, almost always escape.

If the pink, slightly elevated macules of simple purpura are mistaken for the eruption of small-pox, the error is soon corrected by the deeper colour which the macules take on :

The diagnosis of small-pox from chicken-pox—the disease with which it is most often confused—and from vaccinia, has been set out under VESICLES (p. 919). The eruptions of measles and of German measles differ from that of small-pox in that, instead of being papular, they are macular, and that they never pass into a vesicular or a pustular stage. In German measles, further, there is enlargement of the posterior cervical glands, which is never the case in small-pox at an early stage. In scarlatina, the ‘strawberry tongue’ is a sign which is quite different from the condition of the tongue in small-pox. The rose-red lenticular spots which make up the rash of enteric fever are neither so hard nor so

nor, even though the macules may become papules, have the lesions the characteristic hardness of variolous papules. Another point of difference between simple purpura and small-pox is, that in the former affection the face and trunk are seldom attacked, the sites of election being the limbs. In erythema multiforme, although the rash makes its chief attack upon the limbs, it may be widely diffused and may even invade the face. In such cases, however, the diffusion will usually be less general than that of the variolous eruption, nor is the order of incidence the same. With the involution which the erythematous lesions undergo, the resemblance to small-pox ceases. Even in cases of acute febrile erythema, in which the whole cutaneous surface is covered by a profuse eruption, the distribution is quite different from that of the small-pox eruption.

Fig. 543.—Case of septic dermatitis resembling small-pox. (By Dr. Newman Neild.)

Confusion between small-pox and syphilis is much more likely to arise when the syphilide is pustular than when it is vesicular or papular. The erroneous diagnosis may be assisted by the fever and aching symptoms which may precede pustular syphilides, and by the fact that the lesions may begin as papules. In syphilis, however, the constitutional symptoms are less severe, the eruption runs a more indolent course and appears in successive crops, whilst the

vesicles which form on the summits of the papules have an indurated base. Sometimes, too, the syphilitic eruption is indifferent in distribution, and often it comprises various types of lesions, even when it is not distinctly polymorphic, whereas in small-pox the departure from homogeneity is much more limited.

Occasionally impetigo vulgaris is mistaken for mild modified small-pox (Fig. 543), but attention to the points which mark off the former affection from pustular eczema should prevent the mistake. Further differentiating features as between impetigo vulgaris and small-pox are that in impetigo there is no fever, and that the lesions begin as vesicles or bullæ and dry up into flat yellowish crusts. In those cases of sudden and acute eczema which may mimic small-pox, guidance is to be found in the small size

superficiality of the eczematous lesions, the oedema and infiltration of the underlying skin. In scabies, again, the vesicles are superficial, burrows will generally be found, and the heterogeneity of the secondary lesions will aid the diagnosis. In all these affections, the distribution is quite different from that of small-pox, the incidence being partial or patchy. Thus, in impetigo the lesions are frequently confined to the face and extremities, and if the trunk is invaded, it is the front more than the back, the lower part more than the upper. In scabies, except in children, the face escapes, and the commonest sites are the hands and fingers, buttocks, and feet.

In Ricketts' experience, no affection, except chicken-pox, is so frequently confused with small-pox as acne vulgaris, in spite of its chronic, afebrile character, and the absence of subjective symptoms. If, however, the rash is limited to the upper part of the body

Fig. 544.—Pustular eruption, closely simulating small-pox, due to the external application of tartaric Eucalypti ointment. (By Dr. Newman Neild.)

and a few characteristic acne lesions such as comedones are found, small-pox may be excluded.

Copaiba eruption may be mistaken for small-pox. The absence of constitutional symptoms such as pain in the lumbar region and fever, the mixed character of the lesions, and the history are the chief points in the diagnosis.

It is seldom that bromide or iodide eruptions are mistaken for the rash of small-pox. In doubtful cases, attention must be paid to the larger size of the pustules, as compared with those of small-pox, and to the patchy distribution. *Ernest Dore.*

PYREXIA, PROLONGED. A pyrexia may be considered prolonged if it lasts more than ten days : in many cases there are signs or symptoms, or facts in the history, which enable one to make an early diagnosis : in others the precise cause of the pyrexia may remain uncertain for weeks, and the elucidation of the cause may necessitate resorting to more than one special method of diagnosis from amongst the following : -

Blood-counts to determine whether there is leucocytosis or not, and if there is, whether there is a relative polymorphonuclear leucocyte increase suggestive of purulent infection.

Serum tests, especially perhaps Widal's serum reaction for typhoid fever, paratyphoid fever A, paratyphoid fever B : for Malta fever : for dysentery due to Shiga's bacilli or to Flexner's bacilli.

Blood cultures, positive in certain cases of streptococcal or staphylococcal septicæmia or infective endocarditis : in the first week of typhoid fever : and in certain rarer conditions in which the organism is unusual, e.g., *Streptothrix*.

Urine cultures, yielding evidence not only when the urinary tracts are themselves involved, as in coli bacilluria, but also sometimes when the kidneys are healthy but are eliminating living germs from the septicæmic blood-stream.

Bacterial swabbings from any or all of the orifices, with the possibility of discovering a causal germ therefrom.

Lumbar puncture, revealing a case to be meningococcal meningitis, for example, when it might otherwise be mistaken for typhoid fever.

X-rays of teeth or thorax, to exclude dental sepsis or pulmonary tuberculosis which might otherwise be missed.

Rectal and vaginal examination, lest prostatic or pelvic mischief be overlooked.

Therapeutic tests for instance, the influence of quinine in verifying malaria, or salvarsan in verifying syphilis or rat-bite fever, by curing their pyrexias.

The list of conditions that may cause prolonged pyrexia is a long one, and the following includes only the chief :

CAUSES OF PROLONGED PYREXIA.

1. More or less Specific Fevers :

Typhoid fever	Mediterranean or Malta fever	Leptothrix fever
Paratyphoid fever A		Spirochaetosis icterohæmorrhagica (Weil's disease)
Paratyphoid fever B	Secondary syphilis	Tetanus.
Paratyphoid fever C	Influenza	
Typhus fever	Tetragenus fever	

2. Localized Pus :

Prostatic abscess	Empyema of the frontal sinus	Hepatic abscess
Periproctal abscess	Empyema of the ethmoidal air-cells	Cholecystitis
Ishiorectal abscess		Empyema of gall-bladder
Pyosalpinx	Empyema of the sphenoidal air-cells	Suppurative cholangitis
Suppurating ovarian cyst	Periosteal abscess	Suppurative pylephlebitis
Parametritic abscess	Dental abscess	Subdiaphragmatic abscess
Tonsillar abscess	Caruncle	Bronchiectasis
Retropharyngeal abscess	Suppurating glands in neck, axilla, groin	Appendicular abscess
Otitis media	Mammary abscess	Perinephric abscess
Mastoid abscess	Submammary abscess	Diverticulitis abscess
Empyema of the antrum of Highmore	Parotid abscess	Psoas abscess
	Empyema thoracis	Actinomycosis of jaw, cheek, neck, lung, liver, spine, or cæcum.

3. Localized Purulent or Analogous Infections without Pus-collection :

Coli bacilluria	Infective tonsillitis	Infective colitis
Suppurative nephritis	Subacute pharyngitis	Ulcerative colitis
Acute cystitis	Subacute laryngitis	Pancreatitis
Gall-stones	Bronchopneumonia	Meningitis, tuberculous
Phlebitis	Subacute persistent bron-	Meningitis, cerebrospinal
Inflamed hæmor-	chitis	Encephalitis lethargica
rhoids	Parametritis	Polymyositis
Infective rhinitis	Vesiculitis	Erysipelas.

4. Pleurisy with Effusion : Serous : Purulent.**5. Infective Endocarditis.****6. Pyæmic or Septicæmic States** of a type which permits of no more definite name.**7. Tuberculosis :** Pulmonary : Glandular : Arthritic : Peritonitic.**8. Non-purulent Hepatic Affections :** Cirrhosis : Secondary carcinoma.**9. Gout.****10. Rheumatoid Arthritis.****11. Blood Diseases :**

Pernicious anaemia	Mixed leukaemia	Splenic anaemia
Spleno-medullary leukaemia	Lymphadenoma (Pel-Ebstein type)	Banti's disease.
Lymphatic leukaemia		

12. Tropical Diseases, including :

Malaria	Dysentery	Relapsing fever
Trypanosomiasis	Cholera	Sprue
Kala-azar	Plague	Egyptian splenomegaly.

13. Meningeal Hæmorrhage.**14. Pemphigus and Allied Bullous Dermatoses.****15. Rat-bite Fever.****16. Trench Fever.****17. The Persistent Slight Pyrexias of Children.****18. Functional Pyrexia.****19. Fictitious Pyrexia produced by Malingerers.**

Though the list is formidable, clinical acumen assisted by laboratory methods leads to a positive diagnosis in most instances when there is opportunity to watch the case for a time. Space does not permit of a full description of each of the diseases mentioned, but the following are some of the salient points :—

1. Specific Fevers. —

Typhoid fever suggests itself when the patient, previously in good health, suffers from a progressive fever of considerable and increasing degree, starting with headache and malaise, but without many definitely abnormal signs, with a pulse-rate that is relatively slow in proportion to the temperature. The chart is generally of about three weeks' duration apart from possible relapses ; during the first week the rise is each night to a slightly higher level than that of the night before, until a maximum is attained and maintained during the second week, after which there is a progressive diminution during the third week until normal is reached again (*Fig. 545*). A relapse may occur almost before defervescence from the first attack is complete, but more typically there is an afebrile period of about a week preceding the relapse, the latter having all the characters of the first attack but generally milder in degree and extent. There may be a third or a fourth relapse (*Fig. 546*), though this is rare. The illness starts with severe frontal headache and an increasing sense of being unwell ; there may be diarrhoea with foul-smelling stools

of pea-soup consistence, or there may be constipation; the headache lasts severely for about a week, when it almost invariably ceases; the patient will by this time have taken to bed except in mild ambulatory cases. Blood cultures taken thus early give positive growths of Eberth's *Bacillus typhosus*, similar cultures later on proving negative. The spleen becomes palpable, but seldom very large, early in the disease, and remains palpable till defervescence; it enlarges again in a relapse. Other abnormal signs are generally absent, though there may be bronchitic rhonchi at the start. The pneumonic form of typhoid is rare. Typical typhoid rose spots appear, chiefly on the abdomen, less often on the chest or back, and seldom on the limbs, from the seventh day onwards, and in successive crops; there may be only two or three spots altogether, or there may be a dozen or more, but they are pathognomonic: they are rose red, fade on pressure, unlike those of typhus, are about two or three millimetres in diameter, and have no central punctum. Widal's serum reaction—that is, the agglutination of typhoid bacilli by the patient's blood serum diluted 1 in 200—becomes positive in the second week or later, seldom before the tenth day; it is important to test the serum against paratyphoid as well as against typhoid bacilli, lest the disease be due to the former rather than the latter, but a negative Widal reaction does not exclude typhoid fever; occasionally it

Fig. 515. Temperature chart of a typical case of typhoid fever.

remains negative even to the end of the third week, or until a relapse occurs, or altogether. Another help in diagnosis is the fact that typhoid fever gives no leucocytosis, and in the differential leucocyte count the lymphocytes are relatively increased and the polymorphonuclear cells relatively diminished. Rigors are quite exceptional, a fact which sometimes helps in diagnosis from septicæmia, pyelophlebitis, and malaria. The chief conditions apt to simulate, or to be simulated by, typhoid fever are pulmonary tuberculosis, fungating endocarditis, a long-lasting influenza, pyæmic and septicæmic processes, cholecystitis, coli bacilluria, and occasionally tuberculous meningitis. A case in which a dental abscess simulated typhoid fever is mentioned on page 715.

Some difficulty arises in cases in which there has been previous immunization of the patient by previous antityphoid inoculations; the fever is then of shorter duration and the illness mild.

Paratyphoid fever A, paratyphoid fever B, and paratyphoid fever C do not merit individual description; clinically each is almost identical with typhoid fever itself, though possibly milder in type than the main disease; their importance lies, not in their clinical features, but in the fact that the patient's serum will not give a positive Widal's test with typhoid bacilli, but only with the paratyphoid bacillus A, B, or C, respectively; the distinction is of laboratory importance; and when a Widal's test is being made for any suspected case the patient's serum should be tested against all four organisms, and not

against typhoid bacilli only; apart from this the paratyphoid cases are to all intents and purposes the same as typhoid.

Fig. 546. — Temperature chart from a case of typhoid fever in which three relapses occurred without absolute apyrexia in the intervals. The Widal's reaction was delayed, becoming positive only in the eleventh week, up to which time it had been persistently negative. The diagnosis was indicated by the fact that a sister had typhoid fever at the same time and died of it. The patient had been ill two weeks before admission; pyrexia was thus continuous, with the three risings of the relapses, for twelve weeks.

Typhus fever is very rare in England nowadays, though small epidemics occur from time to time even in London. It is associated with poverty and dirt, the infection being

carried by bed bugs. It simulates typhoid fever in its earlier stages, but the termination in favourable cases is by crisis, or partial crisis, soon after the end of the second week, instead of by lysis in the third week or later as in typhoid. Relapses are uncommon. There is no known serum test for the disease. The character of the temperature charts is exemplified by *Figs. 613, 614, p. 786*. The eruption occurring on the fifth day is generally distinctive (*Fig. 327, p. 418*), differing from that of typhoid in that many of the spots are purpuric and therefore do not fade on pressure, whilst some, instead of being superficial, present an appearance of being deep in the skin, a sort of subcutaneous mottling—the mulberry rash, of a brownish rather than red colour, in addition to the mixed rosy and purpuric spots upon the surface: the whole trunk may be covered by the eruption, whereas typhoid fever seldom presents more than a few, or at most a few dozen, spots at any one time. The spleen may be enlarged as in typhoid, but not so constantly. Delirium of a low muttering type is common in the second week—the ‘typhoid state’ being the state of typhus and not the state of typhoid. Infective endocarditis may be simulated: if the pyrexia is prolonged beyond the fourteenth or sixteenth day, typhus is unlikely.

Mediterranean or *Malta fever* is one of the most prolonged of the fevers due to a known specific germ, the *Micrococcus melitensis*: in the undulant form of the disease successive exacerbations of pyrexia may carry on the illness into the sixteenth, eighteenth,

Fig. 546. Temperature chart of a case of Mediterranean fever of undulant type.

or twentieth week or longer (*Fig. 547*). It may simulate typhoid fever closely, including the enlargement of the spleen, and the remarkable paucity of abnormal physical signs; but there are no rose spots or other eruption, and no diarrhoea. The diagnosis may be suggested by geographical factors in the case—recent residence, for instance, in some part of the Mediterranean coast or islands, or Spain, Portugal, the Canary Islands, or parts of South America; especially if the patient has been taking goats' milk, which is the chief medium by which the infection of the disease is transmitted: to clinch the diagnosis one has a serum test, which may be positive from the fifth day onwards, the patient's diluted blood serum agglutinating cultures of the *Micrococcus melitensis* in the same kind of way that a typhoid fever patient's serum clumps typhoid bacilli.

Secondary syphilis may be a definitely febrile illness, so much so that during small-pox epidemics, for instance, it may be mistaken for small-pox. The diagnosis becomes obvious, however, when the roseola is examined carefully, and when it is associated with a fading primary sore, typical snail-track ulcers of tonsils, fauces, and pharynx, and generalized enlargement of most of the palpable lymphatic glands.

Influenza is always a precarious diagnosis except in times of epidemic: especially since doubts have arisen as to whether Pfeiffer's bacillus is the cause. Uncomplicated by definite visceral changes such as pneumonia or gastro-enteritis, the fever is of short duration, lasting from two or three days to a week (*Fig. 548*). Complicated by pneumonia, otitis media, meningismus, or the like, influenzal pyrexia may last a fortnight,

or even a month (*Fig. 549*): and it sometimes does so without any distinctive signs of complications. It may then simulate typhoid fever, tuberculosis, coli bacilluria, streptococcal septicæmia, fungating endocarditis, or trench fever, especially as in the prolonged cases the striking peculiarities of the intense attacks, such as severe pain in the head, at the back of the eyes, in the loins, the prostration, the aching all over, the sudden anorexia, may be absent. The constant presence of influenza amongst us, and the great variety of the characters it assumes, make it difficult to exclude it until positive signs of another complaint manifest themselves, and the diagnosis can often be made positively by a

Fig. 548.—Temperature chart showing the acute onset and short duration of the type of influenza prevalent in June-July, 1918. The patient was already in hospital suffering from a fractured thigh, and caught the infection from a fellow-patient, so that the whole course of the pyrexia could be recorded from the start.

process of exclusion only. One must bear particularly in mind that an apparent attack of influenza may be really the pyrexial phenomena of early but active tuberculous infection, and if at any time during the illness sputum is available, it should be examined for tubercle bacilli.

Tetragenous fever or *septicæmia* is similar to influenza in the symptoms it produces and the course it runs. The pyrexia and the general state of acute illness may constitute the whole phenomena; or there may be complications, as in influenza, such as bronchopneumonia, otitis media, or the like. There may be relapse after apparent recovery. The diagnosis is not possible without blood cultures and the discovery of *Micrococcus tetragenus* in them. *Fig. 550* shows the degree of pyrexia that may be met with. Tetragenous bronchopneumonia in children is another form of the same infection.

Fig. 549. Temperature chart in a prolonged case of influenza in which the pyrexia lasted a month; the diagnosis was confirmed by bacteriological detection of Pfeiffer's influenza bacilli. The case was complicated by influenzal otitis media and transient earache bruits.

Fig. 550. Temperature chart from a case of severe tetragenous septicæmia in an adult. The Widal reaction was negative to typhoid and to paratyphoid. *Micrococcus tetragenus* was recovered on blood culture.

Leptothrix septicæmia has not been recorded frequently, but perhaps it is commoner than is supposed, for it is only diagnosable from other forms of prolonged pyrexia of obscure nature by blood culture. The patient may be very ill, with muttering delirium, retracted head simulating meningitis, and severe prostration making death seem imminent, yet recovery may ensue. *Fig. 551* is a chart from a case in point. Abnormal physical signs may be very few, and the diagnosis would remain in doubt were it not for the positive blood findings.

Spirochaetosis icterohamorrhagica, or *Weil's disease*, is uncommon, but characteristic. It is a severe, often fatal, malady due to a spirochaetal infection spread by rats, and is really a variety of septicæmia in that the spirochaetæ are present in the circulating blood. If blood be taken from the patient early in the disease and injected into a guinea-pig, the organisms may be found in large numbers in the blood and tissues of the latter subsequently a fact that is employed for diagnostic purposes: the patient's blood presently fails to be infective, but the urine becomes so, and urine injections into a guinea-pig may be employed then if the earlier stage of the malady when the patient's blood is infective has been missed. The onset is rapid, and for two or three days the condition may simulate influenza, or possibly pneumonia, especially as herpes labialis is frequent and severe; indeed, few conditions produce such extensive herpes of lips, face, nose, cheeks, chin, and neck as Weil's disease can, the vesicles sometimes becoming hemorrhagic or covered with blood-crusts. About the fourth day jaundice develops, and this, with the herpes and the pyrexia, at once suggests the diagnosis. The jaundice deepens gradually to reach its height about the tenth or twelfth day, after which it begins to lessen and gradually disappear. The

Fig. 551. Temperature chart from a case of leptothrix septicæmia, recorded by Drs. Micheli Clark and Scott Williamson, *Brit. Med. Jour.*, 1912, 67. The patient recovered, but seemed to be at death's door for the time being. Leptothrix was cultivated in pure culture from three separate blood cultures from three different veins, and also from the cerebro-spinal fluid.

Fig. 552. Morning and evening temperature chart in a case of severe spirochaetosis icterohamorrhagica of the secondary fever type, ending in recovery.

temperature is high from the beginning and remains high until about the tenth day, dropping rapidly after the jaundice starts to decrease, but often remaining slightly above normal for a week or ten days before settling completely; in many cases, subsequent to the main fall about the tenth or twelfth day, there are a few days of low pyrexia and then a pronounced secondary fever, without, however, corresponding exacerbation of the symptoms. Fig. 552

is taken from such a case in which, in spite of very severe illness, recovery ultimately ensued.

Tetanus as a cause of pyrexia needs little comment; the diagnosis will be obvious from the trismus and tetanic spasms.

2. Localized Pus. Many cases in which localized pus is the cause of continued pyrexia become obvious as to their nature, if not at once, then after a short period of observation, if careful attention is paid to the parts in which the patient complains of pain or tenderness, and if thorough examination is made. When one is in doubt as to whether actual pus is present, guidance may be afforded by blood-counts, particularly total and differential leucocyte counts when they show leucocytosis and relative polymorphonuclear-cell increase; successive counts showing increasing leucocytosis are very suggestive of pus.

One need not go into detail in regard to the various pus-collections that need to be looked for. Rectal or vaginal examination should serve to detect *prostatic abscess*, *periproctal abscess*, *ischio-rectal abscess*, *pyosalpinx*, *suppurating ovarian cyst*, *parametritic abscess*, all of which are likely to cause local pain in the perineum, anal region, sacral region, back, or lower abdomen.

Tonsillar abscess will be suggested by the appearance of the tonsil on inspection, though chronic cases may escape attention if a thorough examination of both tonsils is not made, especially of their lower poles; for the patient may deny having any sore

throat. Enlargement and tenderness of the lymphatic gland below and behind the angle of the jaw may be a suggestive guide.

Retropharyngeal abscess, if non-tuberculous, is an affection of infancy, and it attracts notice by reason of dyspnoea rather than on account of pyrexia; laryngeal diphtheria may be simulated by the asphyxial cyanosis and stridor. The diagnosis is made by digital examination of the back of the mouth and throat, which is easier than inspection at this age. Tuberculous cases are rare, but occur at a later age as the result of cervical caries, which will also cause stiff neck and pain in the neck; the diagnosis may be established by X-raying the cervical spine laterally (Fig. 619, p. 795).

Otitis media and *mastoid abscess* give rise to acute earache, pain in the ear, and pain, reddening, and swelling behind the ear, the diagnosis depending upon the results of local examination; in severe cases doubt may exist for a time as to whether the trouble has remained local or has spread to become lateral sinus thrombosis or suppurative meningitis; the doubt may be settled only by operation and its result. Fatal pyæmia may result from this as from any other form of local suppuration (Fig. 553).

Fig. 553. Temperature chart of a case of pyæmia, secondary to otitis media and lateral sinus thrombosis. There was a rigor almost daily.

Empyema of the antrum of Highmore may be acute, producing pain and tenderness over the affected maxilla, with oedematous swelling of that side of the face; but in chronic cases the symptoms may be much less definite; there may be face-ache, local swelling, and perhaps a recurrent discharge of pus from one nostril to suggest the diagnosis, however, and it is confirmed by transillumination (Fig. 191, p. 226).

Empyema of the frontal sinus may be acute or chronic, producing pyrexia in either case. The diagnosis may be suggested by complaint of local headache above the eyes, generally on one or other side of the midline rather than central, especially if such headache is associated with local tenderness to percussion; it becomes easy

if the abscess points, as it may do, in the upper part of the inner canthus of the orbit near the root of the nose; but it may remain in doubt for a long time in other cases, even when one has the assistance of a specialist's examination, or of a radiogram of the sinus taken laterally: this should be bright and clean and not opaque. Not a few cases remain undiagnosed because there is insufficient evidence on which to advise surgical opening of the sinus. This applies still more to *empyema of the ethmoidal sinuses* or to *empyema of the sphenoidal sinuses*, from which one gets few objective symptoms. The patient may complain of severe frontal headaches, often worse in the morning and passing off later in the day, and he may notice a purulent nasal discharge coming from somewhere that he cannot locate; pyrexia is often only slight, but it may be of long standing; X-ray examination of the air-cells in the lateral position is only a partial help in diagnosing or excluding pus in them; and one may require diagnosis by puncture of the air-cells at the hands of a nose specialist.

Periosteal abscess will be suggested by the nature of the swelling found upon a bone in which the patient suffers pain. More difficult of detection may be a chronic intramedullary bone abscess, which sometimes causes pyrexia the reason for which may remain obscure for weeks; attention may be drawn to the bone because of the patient's complaint of local aching and pain in it, and an X-ray examination may reveal a lesion which may be thought to be sarcoma until the diagnosis of abscess is confirmed by operation; such an intra-osteal abscess may be present for months before it is detected.

Dental abscess may be indicated by local toothache, swelling and tenderness of the jaw, general swelling of one side of the face, or the occurrence of a gumboil—the latter being nature's method of relieving an apical dental abscess by spontaneous discharge through the outer alveolar covering of the jaw. Many dental abscesses remain latent, however, sometimes for months or years, and they may be responsible for such severe remote effects as generalized rheumatoid arthritis, pronounced anaemia, night sweats, and general ill health. They can sometimes be diagnosed with certainty only by X-ray examination of all the teeth (Figs. 61-63, p. 43); yet the extent to which such

apparently slight trouble may produce pyrexia is indicated by *Fig. 570*, p. 714, from a case in which typhoid fever was simulated and diagnosed until the taking out of one tooth cured the pyrexia and the patient. In no case of prolonged pyrexia in which the cause is not obvious should X-ray examination of the teeth be omitted, lest tubercle or other grave chronic lesion be diagnosed in error from the long-continued low fever.

Carbuncle will be obvious upon immediate examination by the time it has become partly or wholly mature, but after there has been one, others may develop elsewhere without being always obvious at once; the temperature continuing may indicate that further carbuncles are forming, and their site will be indicated by complaint of pain.

Suppurating lymphatic glands will be diagnosed from the character of the tender swellings that precede the skin-reddening and the actual formation of an abscess; the site is likely to be neck, axilla, or groin, and there will usually be an indication of the source of the trouble in the form of a septic focus in the skin corresponding to the lymph-drainage of the gland concerned—impetigo, a septic cut or wound, a whitlow, inflamed external piles, a penile or scrotal sore, or the like. One source of trouble that may be overlooked because of the social status of the patient is *pediculosis* of the scalp: it should be suspected if there is irritation of the back of the neck at the roots of the hair, in association with enlargement of the occipital as well as of the cervical lymph glands; it is a state of affairs that may cause ill health and pyrexia continuing for months.

Mammary and submammary abscess may be of chronic type and cause pyrexia without much pain: the diagnosis depends on local examination of the breasts.

Parotid abscess is rare as a primary condition: as a rule it is a complication arising in the course of other illness, especially after severe operations, or in typhoid fever with oral sepsis: its nature may not be clear until the skin over one parotid gland reddens and the face and neck swell, by which time the pyrexia caused by the parotid infection may have existed already for several days. Pain over the parotid gland or in its neighbourhood will draw attention to the parotitis.

Empyema thoracis is often easy of diagnosis: the abnormal physical signs at the base of one lung, particularly dullness with absence of breath- and voice-sounds, suggest the existence of fluid here: the chest will then be needled and pus found. The condition may be simulated by subdiaphragmatic abscess, but once pus is found the distinction as between its being above or below the diaphragm will be settled surgically. Empyema sometimes arises insidiously, but more often it has a preceding cause, especially pneumonia, and the existence of pus may be suggested by the recurrence of pyrexia when the temperature should be remaining normal (*Fig. 171*, p. 200). Difficulty in diagnosis may be great, however, when the empyema is interlobar, or between the pericardium and the pleura, or between the diaphragm and the lower lobe, or perhaps apical (*Fig. 115*, p. 132) if old adhesions prevent the pus trickling to the base: continued pyrexia may make one feel that pus is present, yet it may escape detection for weeks until one day it is suddenly coughed up and the diagnosis is made clear. Tubercle may have been suspected in the meantime. X-ray examination of the thorax is sometimes most helpful in detecting a buried empyema of this kind.

Hepatic abscess, especially the type following amoebic dysentery, is generally a sub-acute or chronic rather than an acute state of affairs, and the fluctuating pyrexia due to the condition may extend over months. The diagnosis may be suggested by complaint of pain or tenderness over the lower part of the right chest, in front or behind, and by dome-shaped dullness at the base of the right lung, or by friction sounds over the liver; or by the evidence that there is something wrong with the liver in a patient who is known to have had amoebic dysentery in India or elsewhere: but sometimes the patient is unaware of having had any dysenteric infection, abnormal physical signs may be few, and the diagnosis consequently in much doubt. Occasionally the complaint of pain is in the right shoulder, and not in the liver at all—in front of the shoulder-joint when the abscess inflames the peritoneum over the front of the diaphragm, at the point of the shoulder when the centre of the diaphragm is affected, or behind the shoulder when the posterior part of the diaphragmatic peritoneum is inflamed. Sometimes pyrexia and rigors are almost the only phenomena, malaria being simulated: but the existence of more than malaria would be indicated by polymorphonuclear leucocytosis, for in malaria there is leucopenia and a relative increase in the large hyaline corpuscles. The diagnosis

of hepatic abscess is clinched by needling the liver and finding pus, often chocolate-coloured or like anchovy paste: sometimes the existence of the abscess is recognized for the first time when similar pus is coughed up as the result of its ulceration through diaphragm and pleura into a bronchus. Mild cases may be diagnosed by the therapeutic test of giving injections of emetine hydrochloride, the latter sometimes effecting a cure of both the hepatic abscess and its prolonged pyrexia.

Cholecystitis and empyema of the gall-bladder may be considered together, for they are merely different degrees of the same state of affairs. Each may exist without other disease in the gall-bladder, as the result, for instance, of infection by the *Bacillus coli communis*, the *Bacillus typhosus*, or the *Bacillus paratyphosus*: more frequently perhaps the infection is associated either with *gall-stones* or with *carcinoma of the gall-bladder*. There may or may not be jaundice, generally not. Pyrexia may be considerable and prolonged, and rigors from time to time are to be expected. The diagnosis depends largely upon the patient's complaint of pain in the right hypochondrium, associated either with a definitely enlarged palpable gall-bladder or with acute pain and tenderness on palpation of the gall-bladder region below the tip of the right ninth rib cartilage: in severe cases an operation will be performed and the diagnosis confirmed that way.

Suppurative cholangitis is the result of extension of pyogenic infection up the hepatic ducts into the biliary canals within the liver: it generally originates from cholecystitis: when the latter has extended to become suppurative cholangitis the patient becomes increasingly ill, and usually dies of the complaint. The supervention of cholangitis may be indicated by progressive soft uniform enlargement of the liver, associated as a rule with jaundice. Recurrent rigors are the rule.

Suppurative pylephlebitis arises from infection somewhere in the periphery of the portal area—previous appendicitis, for example. Fortunately it is not common, for it is fatal. The liver becomes studded through and through with multiple small abscesses

Fig. 554.—Four-hourly temperature chart in a case of suppurative pylephlebitis supervening on a mild attack of appendicitis. Until rigor occurred, typhoid fever was the diagnosis. Many rigors ensued and some hyperpyrexia. The diagnosis was verified by autopsy.

arising around the subdivisions of the portal vein within the liver. Jaundice is present in less than half the cases, but the liver becomes progressively, smoothly, and uniformly enlarged, and generally tender. The severe pyrexia (Fig. 554), the rigors, the asthenia and wasting, indicate that the patient has developed some form of septic extension from his original disease, but short of post-mortem examination it may be difficult to be certain whether he has, for instance, a subdiaphragmatic abscess or a residual peritoneal abscess

on the one hand, or suppurative pyelophlebitis on the other. There is pronounced leucocytosis in either case.

Subdiaphragmatic abscess is often a most difficult condition to diagnose successfully. It is exceptional for the amount of pus to be so large that it can be recognized with the X rays as in *Figs. 115, 116*, pp. 132, 133. Often the pus is spread about in a thin layer between the liver and the diaphragm, or between the spleen and the diaphragm, so that attempts to locate it by needling may prove unsuccessful. There may be no abnormal physical signs at all; more often there is resultant infection of the pleura, through the diaphragm, leading to impaired percussion note at the base of one lung, accompanied by pleuritic friction and râles; the doubt will then be as to whether there is pleurisy only, or pneumonia, or an empyema, or a subdiaphragmatic abscess, and most difficult it may be to decide between them. With the last the patient becomes progressively more ill and emaciated than with the others, and it may become a question of a secondary operation to see if pus below the diaphragm can be found; if it is there and not found the pyrexia continues and the patient loses ground slowly but steadily, and dies.

Bronchiectasis may be responsible for quite prolonged periods of pyrexia with afebrile intervals of varying length. The pyrexial bouts are due either to invasion of the pus-containing cavities by fresh organisms, or to recrudescences in the activities of the germs already present. The abnormal physical signs in the lungs, the abundant foul sputum, and the clubbed fingers indicate the diagnosis; though it may be difficult to differentiate an empyema ruptured through the pleura into a bronchus from a pure bronchiectasis.

Appendicular abscess may be easy of diagnosis, simply on palpating the tender swelling in the right iliac fossa; or it may be difficult by reason of the abscess being behind the caecum or otherwise tucked away; rectal examination leads to the detection of the abscess when it descends into the pelvis. Operation will generally be resorted to at the start, pyrexia ceasing as a rule when the pus obtains free drainage, so that it is exceptional for appendicular abscess to be the cause of prolonged pyrexia; there is, however, great difficulty sometimes in deciding whether, in a given case of prolonged slight pyrexia, chronic appendicitis is the cause of the fever. That a chronic appendix may be responsible is beyond doubt, but there is perhaps too great a tendency to think of chronic appendix trouble as the likely cause of vague abdominal discomforts associated with ill health without more evidence, perhaps, than a wincing on the patient's part when the right iliac fossa is palpated fairly vigorously; before removal of the appendix is advised it is important to exclude other possibilities, such as coli bacilluria or tuberculous iliac lymph glands, and to have something positive in the way of resistance or rigidity in the right iliac fossa.

Perinephric abscess is less common than is perinephritis with perinephritic œdema; both may cause pyrexia of considerable degree and possibly lasting for weeks. Pain in the loin is almost always present, with tenderness to palpation both in the loin and in the lumbar region. There may be no defined tumour, but only a sense of resistance; the latter may be evident when, with the patient recumbent, the examiner places one hand behind each loin with the finger-tips external to the erector spinae muscles, and then makes as if to raise the patient from the bed though without actually lifting him; the fingers on the affected side will not feel the hollow of the loin clearly as will those on the sound side. If the patient is well enough to sit up in bed with the back bared, and the observer then looks down his spine from above, it may often be apparent that, whereas the loin on the sound side is slightly concave, that of the perinephric abscess side is either flat or actually slightly convex; only in pronounced cases does the loin show a pronounced convexity as in *Fig. 555*. Perinephric abscess is generally the result of pyogenic infection within the kidney, indicated by routine examination of the urine secondary to coli bacilluria, for instance; or it may be due to pus tracking up behind the colon from appendicitis; or it may be a delayed result of a loin injury, caused at football, perhaps, or from a stumble against a bannister-rail, a hematoma due to the injury becoming infected and slowly forming a perinephric abscess weeks or months after the trauma.

Diverticulitis abscess may be subacute and associated with long pyrexia; generally it is in the left lower part of the abdomen, producing a tender tumour that may simulate carcinoma. It is preceded by chronic bowel symptoms, constipation, and colic; the diverticulitis may have been demonstrated by reason of the isolated remnants of barium seen in diverticula after the main mass of a barium meal has been evacuated (*Fig. 141*, p. 162);

or else the diagnosis depends on what is found at operation. It is a disease of the second half of life, not of the young.

Psoas abscess results from tuberculous spinal caries : the condition may be apyrexial, but, like any other form of tubercle, it may cause irregular pyrexia over a long period even when it has not been opened. If operation is performed secondary infection may, if great care be not taken, lead to a febrile course of long duration. Pain localized to some part of the back and stiffness of the corresponding part of the spine may lead to

Fig. 555. Deep-seated perinephric abscess bulging the left loin.

discovery of the caries by X rays (Fig. 480, p. 628) before there is any kyphosis : or the diagnosis may remain unsuspected until a tender swelling begins to appear above or below one groin as the abscess tracks down from the spine along the course of the psoas muscle, ultimately giving fluctuation from above to below Poupart's ligament. It is a malady of the young.

Actinomycosis (Fig. 450, p. 563) is diagnosed by the discovery of the ray fungi (Fig. 610, p. 779) in the discharge emerging from a sinus communicating with the focus infected, generally the cheek, jaw, neck, lung, liver, caecum, or spine. It may occur anywhere in the skin or viscera, however, and if bacterial methods of diagnosis are not resorted to the true nature of the disease may be missed. An ischiorectal abscess, for instance, may be regarded as of merely pyogenic origin and yet be really actinomycotic. There is diffuse infiltration of deep as well as superficial parts, liability to discharge through more sinuses than one, and a suggestive purplish-red colour of the skin adherent to the lesion. The course is chronic, often apyrexial, but frequently there are periods of pyrexia analogous to those seen with tubercle.

Erysipelas, though generally of short duration, sometimes causes pyrexia lasting more than a fortnight (Fig. 556).

3. Localized Purulent or Analogous Infections without Pus-collection.—

Coli bacilluria may be chronic and apyrexial, but it is liable to exacerbations with prolonged pyrexia (Fig. 448, p. 560), the diagnosis being suggested by the aching or pain in one or both loins, the frequency of micturition, and the pain during micturition, and confirmed by recovery of the *Bacillus coli communis* from specimens of urine obtained by catheter. It may exist, however, with so few symptoms of urinary disease, especially in girls and children, that its causal connection with continued pyrexia may be missed if the condition is not remembered and looked for. It is not likely if the urine is perfectly clear and free from albumin; opalescence of the urine, a faint haze of albumin, and excess of leucocytes microscopically would point to the need for urine cultures.

Suppurative nephritis is a more serious malady; doubtless there are multiple minute abscesses in the kidneys in some cases of coli bacilluria, but by suppurative nephritis one understands a graver condition in which the kidney substance becomes streaked and spotted with infective pus, usually as the result of ascending infection from acute cystitis, enlarged prostate, or urethral stricture. Pain in the loins may or may not be present; the urine is purulent, yields the causal germ on culture, the patient is very ill, with rigors and high, long-continued pyrexia.

Acute cystitis does not always cause pyrexia, but it generally does; there is pain in the hypogastrium, increased if the patient holds his water for any length of time, great frequency of micturition, often rigors; the urine is often foul-smelling as well as purulent, and shreds and bits of vesical mucosa may be found in it microscopically. The surest way of establishing the diagnosis is by cystoscopy under an anæsthetic. The lesion may be primary, or secondary to tubercle of the bladder, calculus, or carcinoma.

Gall-stones depend for their inception upon preceding microbial infection of the gall-bladder; the infection may die out and leave sterile gall-stones, but quite often there is residual latent cholecystitis, accounting for the way in which certain gall-stone cases may exhibit irregular but sometimes prolonged pyrexia, and for the occurrence of pyrexia in biliary colic attacks.

Phlebitis of a superficial vein is indicated by the tenderness, with or without redness and swelling, along the course of the vein itself; pyrexia of variable degree and duration accompanies the malady in the earlier stages. The diagnosis is much less easy when the inflamed vein is a deep one; even in the leg phlebitis of a deep vein may produce no more decided symptoms and signs than pain deep-seated in the affected part, but usually there is a certain amount of unilateral œdema of the foot or calf to indicate the nature of the trouble. When, however, the inflamed and clotted vein is an internal one, for instance in the abdomen, it may be impossible to diagnose what is wrong with any certainty. That intra-abdominal phlebitis and thrombosis are not uncommon is shown by those catastrophic cases of sudden death from pulmonary embolism about ten days after operation or childbirth; and also by the frequent discovery of calcareous phleboliths in the course of routine post-mortem examinations. It is not unlikely that intra-abdominal phlebitis is responsible for both continued pyrexia and vague but possibly severe abdominal pain in certain cases of otherwise apparently straightforward laparotomy. Venous thrombosis in the pelvis, not necessarily associated with white leg *phlegmasia alba dolens* may account for harassing pyrexia after childbirth.

Inflamed hemorrhoids are really but a variety of phlebitis; the diagnosis is made readily upon local examination.

Infective *rhinitis*, *tonsillitis*, *pharyngitis*, and *laryngitis* are diagnosed by local inspection; the infecting germ by bacteriological methods. Secondary syphilis of the tonsils and pharynx needs to be thought of, for it also may be pyrexial.

Bronchopneumonia is diagnosed from the abnormal physical signs in the chest; it may be of short duration—a week, for example; but it generally lasts considerably longer,

Fig. 556. Temperature chart of a case of facial erysipelas following a septic scratch.

ending not by crisis as does lobar pneumonia, but by lysis: the pyrexia may last for two, three, or more weeks: and there may be relapses. The continuance of the pyrexia may raise doubts as to whether an empyema may not be present as well, in which case needling of the chest would probably be resorted to: or as to whether there may not be tuberculous mischief, a doubt that may be settled by sputum testing, or by continuing to watch the course of the disease. Acute miliary tuberculosis of the lung may start as what seems to be influenza, continue as an apparent bronchitis, passing in the course of some weeks to bronchopneumonia, and even then it may not be clear that the patient has so fatal a malady, for the sputum may remain persistently negative as regards tubercle bacilli if no main focus in the lung is 'open'.

Subacute persistent bronchitis is still more difficult to diagnose with certainty to the exclusion of phthisis. Some patients may have pyrexial bronchitis, especially in the winter months, for weeks on end: on the other hand, senile phthisis often appears to be no more than chronic bronchitis and emphysema, the course being slow and insidious, though cough, sputum, and pyrexia may all be pronounced. Tubercle bacilli should be sought in sputum as a routine thing: when none are present, cultural methods should be employed to determine the microbial nature of the bronchitis. It is often wise to X-ray the chest too, to exclude such opacities as might be expected if an aneurysm, or tubercle, or cancer of the lung were simulating bronchitis.

Endometritis and *parametritis* are diagnosed by pelvic examination: the latter is likely to be the after-effect of recent labour: it is often associated with continued pyrexia, pain in the pelvis and lower part of the back, and it may go on to the formation of an abscess. Chronic endometritis is not usually pyrexial, but the acute forms are, particularly when they result from retained products of conception, after abortion, miscarriage, or labour. Elderly women are apt to develop a purulent form of endometritis, sometimes pyrexial, with pelvic pain, bearing-down pain, pain in the back, a foul vaginal discharge, often blood-stained, the condition simulating advanced carcinoma of the body of the uterus.

Vesiculitis is generally due to gonococcal infection of the seminal vesicles, though it may be septic. The complaint is mainly of hot burning pain in the rectum, made worse by the passing of a motion. Proctitis is simulated, or carcinoma of the rectum or acute prostatitis. Diagnosis is made by rectal examination, the finger locating the painful swelling in the vesiculae seminales.

Colitis, whether infective or ulcerative, will be suggested by the history of diarrhoea with the passage of blood and mucus per anum, associated with pain along the course of the colon, particularly the descending colon. Carcinoma of the colon may be simulated, or diverticulitis. The diagnosis is easy if the affected mucosa can be seen with the sigmoidoscope; but if the lesion lies farther up it may be difficult. X rays may show that there is no obstruction such as carcinoma generally produces, and assist the diagnosis by exclusion; but one depends mainly upon the history and upon what one sees with the sigmoidoscope.

Pancreatitis when it is acute is a surgical emergency: when subacute or chronic it is very difficult to diagnose. It is not always pyrexial, but it may be. It may simulate such things as gall-stones or tuberculous peritonitis or abdominal lymph glands. It will suggest itself at once if there is glycosuria in association with pyrexia and a dull aching pain in the abdomen across the site of the pancreas, but the symptoms are generally too vague to be characteristic. There is often a curious dull-brown pigmentation of the skin that is suggestive; and a certain amount of diagnostic help can be got from examination of the stools for split and unsplit fats and for protein residues (see CAMMIDGE'S PANCREATIC REACTION, p. 128). It is difficult to be sure, however, how much reliance one can really put upon the interpretations given to the results.

Meningitis, whether *tuberculous* or *meningococcal* (cerebrospinal), will be suggested by the occurrence of symptoms of increased intracranial pressure of rapid onset—headache, giddiness, vomiting, convulsions, optic neuritis, strabismus, head-retraction, Kernig's sign (*Fig. 577*, p. 732). The diagnosis will be established by examination of the cerebrospinal fluid after lumbar puncture. Pyrexia may be slight or even non-existent in tuberculous cases until the last stages are reached, depending more on the general miliary tuberculosis than upon the meningitis; in cerebrospinal cases fever may be both marked and

prolonged, though curtailed by injections of antimeningococcal serum. *Fig. 557* is from an acute case in which recovery was speedy; *Fig. 558* from a case that began gradually, but was long drawn out, though finally ending in recovery.

Encephalitis lethargica is not necessarily pyrexial, but usually there is some fever and it may be high; there is, however, nothing characteristic about the chart. The onset may be acute, in a way that resembles meningitis; on the other hand, it may be insidious, the patient merely becoming drowsier each day until presently he is difficult to wake. The symptoms are protean, depending upon what part of the cerebrum, mid-brain, cerebellum, pons Varolii, or medulla oblongata is most involved by the inflammatory process. There may be strabismus or other cranial-nerve paralysis. A severe case may become comatose and remain so for weeks; a mild case may pass almost unrecognized until some change in the mental characteristics, or some unusual tremor of arm or leg, calls attention to the fact that something has happened. The diagnosis depends upon

Fig. 557. Temperature chart, taken four-hourly, from a case of acute meningococcal (cerebrospinal) meningitis recovering rapidly under serum treatment. L.P., Lumbar puncture.

Fig. 558. Temperature chart, taken four-hourly, from a case of cerebrospinal meningitis which began insidiously, became severe, lasted long, but ultimately recovered. The chart illustrates how, even weeks after the main illness, there may be little rises of temperature. L.P., Lumbar puncture.

there being some symptom or sign that suggests an intracranial lesion, especially drowsiness or coma ('sleepy sickness'), with negative findings as a rule in regard to cerebrospinal fluid and optic discs. A case that recovers after appearing for a time to be some form of meningitis, without any positive findings in the cerebrospinal fluid, is very likely to be one of encephalitis.

Polymyositis acuta is a rare malady in its fully-developed form, but mild cases are probably common under the label 'rheumatism'. The mild type survives, but the severe acute type is often fatal. As a general rule the inflammatory trouble is not confined to

the muscles, though acute pain and stiffness in the latter, with prostration, constitute a big part of the clinical picture; inflammatory mischief in the skin, mucous membranes, nerves, spinal cord, or serous membranes may be associated with the myositis to varying degrees in different cases, with the result that many names have been used in describing the malady; for instance, neuro-myositis, dermato-myositis, dermato-neuro-myositis, neuro-mucoso-myositis, dermato-mucoso-myositis, sero-dermato-myositis, sero-mucoso-

neuro-dermato-myositis, and so on. When the skin is affected as well as the muscles the patient develops areas of marked reddening, similar in appearance to erysipelas, but differing from the latter in that the reddening, varying perhaps in degree to some extent, may last for weeks in the same place; in the case from which *Fig. 559* and the temperature chart in *Fig. 560* were taken the face remained in a state of what looked like chronic erysipelas for over two months. When mucous membranes are involved, severe vomiting or intractable diarrhoea, or both, may be prominent phenomena, which cease, however, long before the myositis does if the condition does not end fatally. When serous membranes are attacked, acute pericarditis, sometimes hemorrhagic, is commoner than pleurisy, and both are commoner than peritonitis; the pericarditis cases all die.

Fig. 559.—Acute dermato-myositis in a boy.

The nervous phenomena consist partly in extreme pain in particular nerves, partly in vague departures from the normal as regards the reflexes, indicating lesions in the cord or brain that are not specially localized. The myositic phenomena are constant; erysipelatoid phenomena in the skin frequent; the gastro-intestinal phenomena not

Fig. 560. Temperature chart from the case of acute polymyositis of which *Fig. 559* is also an illustration. He could not use a single muscle because of the pain; the muscles could be felt to be infiltrated and hard. Trichinosis was the original but mistaken diagnosis.

infrequent; the serous membrane events rarer but generally fatal; the nerve symptoms vaguer and inconstant. The whole illness is pyrexial, severe and prolonged. It seems not unlikely that generalized streptococcal infection is at the root of the trouble, and perhaps the shortest way of summarizing the symptoms would be to say that the patient

presents, as it were, a combination of acute trichinosis with chronic erysipelas. There is, however, no eosinophilia as there is in trichinosis; and the erysipelatoïd areas remain long and do not become covered by blebs or bullae as in erysipelas. The muscles become too painful to be used at all; the patient cannot lift an arm or a leg; he cannot laugh because his diaphragm and his face muscles hurt him so; he can hardly eat; he is entirely prostrated. If he survives, there are generally deformities from fibrotic fixations of the substance of the muscles, and various contractures and disabilities, but these differ from the effects of rheumatoid arthritis in that they are not specially related to the regions of the joints. It is not impossible that *myositis ossificans* is a related malady, though in this the attacks of pain and pyrexia and muscle inflammation are recurrent over a period of years, each attack being more or less local to a particular muscle or part of a muscle, but affecting a new place on each fresh occasion; the focus thus attacked suffers from a deposition of lime salts when the myositis subsides, so that a hard bone-like mass takes the place of what was originally muscle; the patient ultimately develops 'ossification' (really calcification) of nearly all his muscles—the ossified man.

4. Pleurisy with Effusion. Pleurisy with effusion is associated with pyrexia; the diagnosis depends, not on the course of the fever, but upon the abnormal physical signs in the chest, and it is confirmed by finding the fluid on needling. An empyema may be

FIG. 561. Temperature chart in a case of acute 'simple' pleurisy with effusion, in which paracentesis thoracis was performed twice. The fluid was serous and clear; the cause was not ascertained, a guinea-pig inoculated with some of the fluid remaining free from tubercle, and the fluid itself yielding no growth of micro-organisms on culture. The continuance of the pyrexia for between three and four weeks, with gradual lysis, is typical.

suggested by the continuance of pyrexia after the crisis of lobar pneumonia (Fig. 171, p. 200), but the fever ceases when the pus is let out; when an empyema is 'buried' (p. 133) it may be difficult of detection, unless found by X-ray examination (Fig. 115, p. 132) or unless it is suddenly coughed up; and pyrexia may continue for a long time if an empyema is present and not detected. In the case of serous effusion of the type often termed 'simple'—that is to say, without concomitant obvious disease to produce it, growth for instance, or leukaemia, or something of that sort—the pyrexia generally lasts for between three and four weeks (Fig. 561), is not obviously influenced by tapping the chest, and it tends to end by gradual lysis. Such 'simple' effusions are frequently indicative of latent tuberculosis of the lungs.

5. Infective Endocarditis. Infective or fungating or malignant endocarditis is seldom an acute disease nowadays in the way it used to be when it was a complication of septic surgery and was known as being mainly of either the 'pyæmic' or the 'typhoid' types; both severe and of a few weeks' duration, the former with rigors, the latter without. Nowadays the type is far more often of the subacute or chronic variety—*endocarditis infectiva lenta*—a heart case in which for a time it may seem that there may be merely

chronic valvular disease without infection until one or other of the events described on p. 46 leads one to the view that the condition is much more grave—progressive and almost certainly fatal fungating endocarditis. The two most suggestive points about such a case are: (1) Enlargement of the spleen, always a danger sign in a heart case; (2) Some form of pyrexia, no matter what the type. Ordinary chronic heart disease is apt to be associated with hypothermia (p. 391), a normal base-line of about 97° ; hence even 98.4° F. may be pyrexia in such a patient, and even the slightest rise above this merits respect and leads to anxiety unless some obvious cause such as tonsillitis or pleurisy or recurrence of acute rheumatism can be found to account for it. The difficult cases are those in which there is no bruit, for the heart may then not be under suspicion, and it may be weeks or months before the diagnosis becomes clear. Blood cultures may or may not be positive. When there is a bruit of organic type, especially if the spleen

Fig. 562.—Twenty-four weeks' temperature chart, taken morning and evening, in a case of fungating endocarditis which developed in connection with post-rheumatic mitral stenosis. The liability to hypothermia in the later stages of the malady, as the patient becomes more and more toxic and asthenic, is pronounced.

is enlarged too, the occurrence of any form of pyrexia that cannot be explained by some demonstrable collateral lesion is bound to raise fears of infective or fungating endocarditis. The course of the disease is slowly downhill; it may last for weeks, months, or even over a year, for it is not frequently acute; there may be remissions or apyrexial intervals (*Fig. 65*, p. 46) raising false hopes; but if there should be pyrexial relapses, and still more if the pyrexia continues week after week (*Fig. 562*), the diagnosis and its grave consequence can scarcely be escaped, even if the general condition of the patient may, for the time, seem to be not so bad. There is every conceivable sort and kind of pyrexia in these cases; the point is that any sort of pyrexia whatever is of grave omen.

6. Pyæmic or Septicæmic States of a Type which Permits of no Definite Name.

Apart from acute septicæmia resulting from obvious causes such as post-mortem wounds, the pricking of a finger at an operation, infection during or after childbirth, a mosquito- or gnat-bite, and so on, one meets more frequently nowadays than formerly with cases of severe and long-drawn-out pyrexial illness in which the patient may be almost at death's door for weeks or months yet ultimately recover. Some such cases yield streptococci

Fig. 563. Four-hourly temperature chart during the last three months in a fatal case of tuberculous peritonitis without effusion in a boy of 8. Death occurred from exhaustion, and towards the end the temperature was less than previously. Post mortem the intestines were matted together by adhesions and caseous tuberculous masses; the mesenteric and other abdominal lymphatic glands were enlarged and caseous, and so were many of the bronchial and mediastinal glands. There was no pulmonary tuberculosis.

on blood culture, and doubtless all are a variety of subacute or even chronic septicæmia, but it is often difficult or impossible to decide whence the infection originated. During the course of the illness all manner of intercurrent complications may develop: pleurisy, for instance, now on one side, now upon the other, with or without effusion: the pleurisy clearing up whilst the general pyrexial illness continues: there may be attacks of pain in the abdomen with symptoms suggesting pancreatitis, or perisplenitis, or local peritonitis: or again phlebitis, or pericarditis, or indeed intercurrent inflammation almost anywhere. Purpura may occur in the skin, or pyuria, and yet one cannot say that the disease lies in any one place or organ. A bruit may develop to suggest infective endocarditis, and then disappear again. The cases might almost be described as comparable to long-drawn-out infective endocarditis, yet without the actual endocarditis: gravely ill though the patient may be for weeks or months, recovery is possible, and hope should not be given up. There is no concise name for the condition, and although it is a variety of septicæmia or blood-poisoning, it is of a type differing from what one ordinarily thinks of when the word 'septicæmia' is used.

7. Tuberculosis.—Tuberculous lesions, whether pulmonary, glandular, arthritic, or peritonitic, often exist without any pyrexia at all: on the other hand, any form may produce pyrexia, and sometimes the existence of some degree of fever without anything apparent to account for it may be almost the sole evidence that such disease is present (see PYREXIA WITHOUT OBVIOUS CAUSE, p. 711). Pulmonary tuberculosis is generally pyrexial in the later stages, when the fever is caused as much by secondary infection of the lung cavities by streptococci, pneumococci, staphylococci, Friedländer's pneumobacilli, *Bacillus pyocyaneus*, and others as it is by the tubercle bacilli themselves: earlier there are often long periods of apyrexia even when the tuberculous process is active, though there are often brief febrile spells of influenza type—the 'pousses évolutives' of the French. Arthritic tuberculosis is often apyrexial if the joint is not opened or if no sinus has developed leading to secondary pyogenic infection. Glandular tuberculosis is less liable to be pyrexial when the glands involved are cervical or bronchial than when the mesenteric and other abdominal lymphatic glands are caseous and softening: though tuberculous glands anywhere may be responsible for fever. It is difficult to say where tuberculosis of the abdominal lymphatic glands ends and tuberculous peritonitis begins, the latter being nearly always associated with caseation of the mesenteric glands ('tabes mesenterica') and probably arising from them: whether ascitic or dry, there may be prolonged pyrexia (Fig. 563). The diagnosis may be easy if there is ascites in a child or if there are palpable abdominal masses which do not seem to be malignant, or if there is a spontaneous fistula at the umbilicus: but it may be difficult if there are no lumps and no ascites, merely a pyrexial state of ill health with vague abdominal pains which may be mistaken for chronic appendicitis or other non-tuberculous trouble in the abdomen. The patients are nearly always young, often children, and the general look of the facies may suggest that the pyrexia and the abdominal symptoms have a tuberculous basis.

8. Non-purulent Hepatic Affections. Quite apart from fever that occurs in obviously infective lesions of the liver, such as hepatic abscess, cholecystitis, cholangitis, and pylephlebitis, there is liability to pyrexia, generally without the ordinary concomitants of

Fig. 561. Temperature chart of a case of sarcoma of the neck and mediastinum.

fever, when the liver tissue is affected by lesions which are not obviously pyogenic, particularly *cirrhosis* and *secondary carcinoma*: the kind of pyrexia met with in these conditions is exemplified by Fig. 66, p. 47, and Fig. 323, p. 408. The appetite may be fairly good, and the patient may even be carrying on his ordinary work although his health is

failing: the existence of pyrexia might be unknown if the thermometer were not being used in the course of usual routine. Pyrexia may also occur from new growth elsewhere than in the liver, as in the case charted in *Fig. 564*, in which the lymphosarcoma led to pyrexia of over four months' duration.

9. **Gout.** The fact that acute gout may be a decidedly pyrexial illness is sometimes forgotten, with the result that suppurative arthritis may be diagnosed in error, and the inflamed tissues incised in the expectation of finding pus. Many a gouty inflammation has been operated upon as a result of this misconception. *Fig. 330*, p. 424, shows the kind of pyrexia acute gout may produce, and the symptoms of the malady are detailed on p. 428.

10. **Rheumatoid Arthritis.** There is a great tendency to use the term 'rheumatoid arthritis' still for a case when the actual *-itis* (inflammation) has long since died out and the patient is suffering from deformed and mechanically painful joints resulting from previous arthritis now obsolete. Such deformed and even painful joints are not actually

Fig. 565. Characteristic temperature chart of a case of pernicious anemia.

rheumatoid arthritis, any more than a joint fixed by callus after a previous fracture is still a fracture: in the late stages there is no pyrexia and the treatment is purely orthopaedic; in the original disease, on the other hand, when actual inflammatory peri-arthritis is still in existence, when medical and antibacterial treatment and rest are indicated, there is nearly always pyrexia, generally of low degree but long-continued. The actual pyrexia may attract but little notice, but it is very important, because it indicates that the disease is still active and in a stage that calls for very different treatment from that which is required when the activity has died out and one merely has the orthopaedic question of how best to deal with joints fixed and deformed by a disease process which has by then itself ceased to be active.

11. **The Blood Diseases.** Any one of the severe blood diseases may be associated with prolonged pyrexia, but the diagnosis depends upon other factors, particularly the blood-count, as in *pernicious anemia* (p. 30) and *leukæmia*, whether splenomedullary, lymphatic, or mixed (pp. 32-35). Temperature charts of pernicious anemia are illustrated in *Fig. 565*; and of leukæmia in *Fig. 47*, p. 34, and *Fig. 569*, p. 713. *Lymphadenoma*

or *Hodgkin's disease* may produce no pyrexia, or merely a prolonged and irregular pyrexia of the same type as may be met with in leukemia; or it may produce a particularly striking form of regularly recurrent pyrexia with apyrexial intervals, of the type generally spoken of as *Pel-Ebstein's disease*; the latter is merely lymphadenoma with this peculiar type of temperature chart (*Fig. 566*). The same patient may exhibit the relapsing type of pyrexia at one period and a much less regular type of fever at another.

Splenic anemia and *Banti's disease* are discussed under **SPLEEN, ENLARGEMENT OF** (p. 780); each may be apyrexial, but either may cause continued pyrexia of precisely the same type as that which may be met with in cirrhosis of the liver (*Fig. 66*, p. 47).

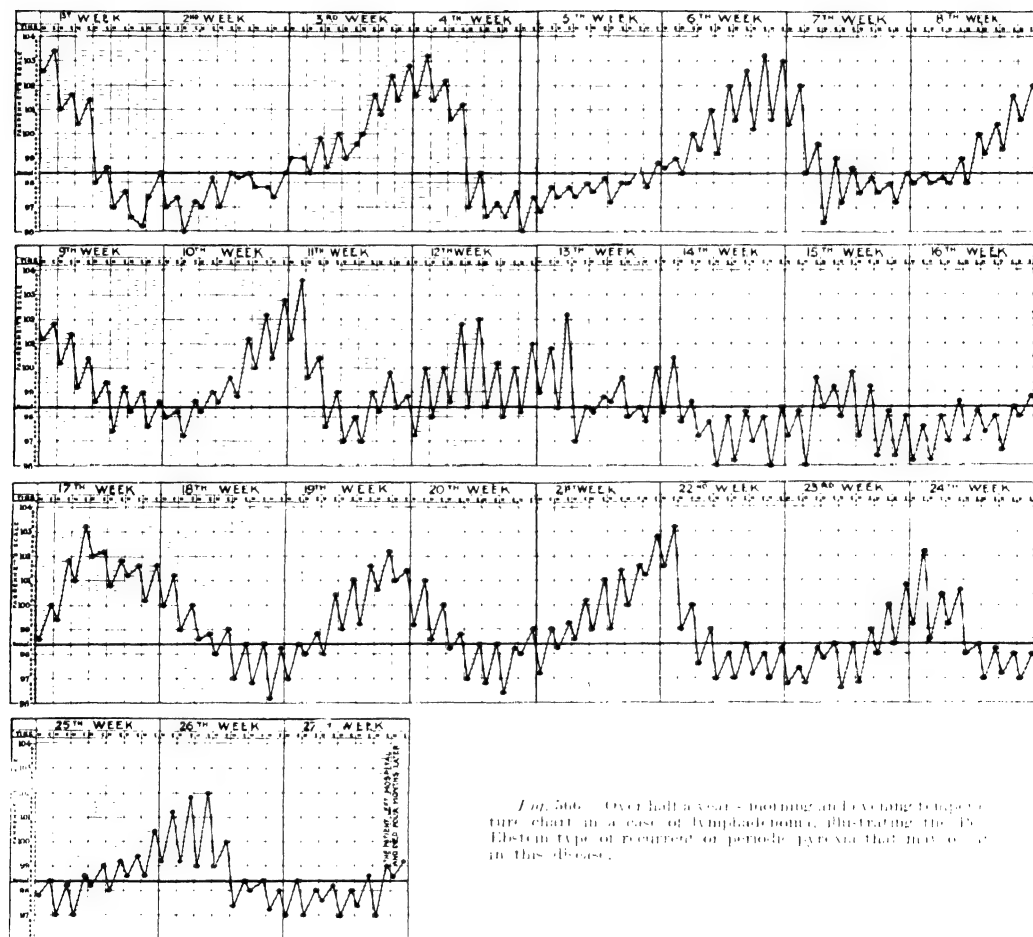

Fig. 566.—Over half a year's morning and evening temperature chart in a case of lymphadenoma, illustrating the Pel-Ebstein type of recurrent or periodic pyrexia that may occur in this disease.

12. Tropical Diseases.—*Malaria* is discussed on p. 37; diagnosis depends on the discovery of malarial parasites (*Figs. 57-60*, pp. 40, 41), in blood films.

Trypanosomiasis need not be pyrexial; infection may be latent for a long time before the parasites invade the central nervous system and lead to the drowsiness, torpor, coma, and death of sleeping sickness. There are pyrexial bouts in the course of the illness, however, and malaria may be simulated. The diagnosis may be suggested by conditions of residence—in Uganda, for instance, where the tsetse fly (*Figs. 49, 50*, p. 37) is found, the parasites being transmitted by the bites of this insect; it is confirmed by the finding of the trypanosomes in blood films, or, in the final sleeping stage, in the cerebrospinal fluid.

Kala-azar is a disease that emanates mainly from Assam, though patients may return to England with it, for it may last for weeks or even months before its usually fatal

termination ensues. Some cases have been cured by stibenyl injections. There is no characteristic chart, but pyrexia, often extreme, is of the swinging but continued type; great enlargement of the spleen with continued pyrexia in a patient from Assam would suggest the diagnosis, the latter being confirmed by discovering Leishman-Donovan bodies (immature trypanosomes) (*Fig. 605*, p. 779) in slides made from material obtained by spleen-puncture.

Dysentery is diagnosed from the severe diarrhœa and the blood and mucus in the stools; the variety being determined either by discovering *Amœba histolytica* in the motions examined fresh upon a warmed stage under the microscope, or amœbic cysts which need special knowledge for their verification; or, in the bacillary forms, by bacteriological cultural methods which are complex and difficult, or by finding that the patient's blood serum gives a positive agglutination test either with Shiga's or with Flexner-Harris bacilli. The chief difficulties arise in cases that have become chronic; periods of low fever may occur when there are mild exacerbations of the original dysentery, and it may be difficult to decide whether such pyrexia is due to the dysentery or to something else—malaria, for example.

Cholera will seldom arise in an isolated case; it is generally epidemic; the diagnosis is verified by discovering the cholera vibrios in the rice-water stools.

Plague is also epidemic; its types are various, the two best known being the bubonic and the pneumonic. The diagnosis depends on discovering plague bacilli in fluid obtained by puncturing a bubo, or in the sputum, by special bacteriological methods. The pneumonic form is the more acute and it may simulate ordinary lobar pneumonia; the bubonic form is of longer duration with less high pyrexia. Both cholera and plague, when they occur in England, are likely to develop in connection with persons coming from India or the East, particularly amongst members of ships' crews.

Relapsing fever has a characteristic temperature chart (*Fig. 48*, p. 36); very rare in England, it is met with chiefly in the Near and Far East; the diagnosis turns partly on the relapses shown in the fever chart, and partly on discovery of Obermeier's spirochaetes in blood films.

Sprue is pyrexial in its earlier phases, but seldom so by the time patients return with it from India or the East, where it is usually acquired. There is no certain bacteriological test for the disease; the diagnosis is suggested by the initial sore tongue and mouth, and the subsequent troublesome diarrhœa with peculiar abundant frothy stools, free as a rule from the blood and mucus of dysentery.

Egyptian splenomegaly is allied to splenic anæmia (p. 49) and Banti's disease; it might be described as Egyptian Banti's disease. Starting with enlargement of the spleen without any other symptoms or signs, there is presently a second stage when the splenomegaly is associated with anæmia, and slowly progressive loss of health and strength, like splenic anæmia; until the third stage, with ascites, is reached in the course of some years, and the patient dies of cirrhosis of the liver as does a Banti's disease case. What the special cause in Egypt may be is scarcely known, but the malady may be cured, as splenic anæmia is, by splenectomy before the ascitic stage is reached. Almost any stage of the malady may be accompanied by low but prolonged pyrexia, similar to that of ordinary cirrhosis of the liver (*Fig. 66*, p. 47); on the other hand, there may be long apyrexial intervals.

13. Meningeal Hæmorrhage. Almost any malady that interferes radically with the heat-regulating centres in the brain may cause pyrexia, often without the other symptoms usually associated with fever; as a rule death or recovery renders such types of pyrexia of short duration, as seen, for instance, in cases of pontine hæmorrhage. Sometimes, however, the active cause, after a head injury for instance, may be not incompatible with recovery; or the patient may survive long enough to come into the category of cases of pyrexia of some length. *Fig. 567* is from such a case in which, after a head injury without fracture, a diffuse infiltrating subarachnoid hæmorrhage was found post mortem.

14. Pemphigus and Allied Dermatoses. These are discussed in the article on BULLÆ (p. 123); there is less liability to pyrexia in dermatitis herpetiformis, herpes gestationis, and erythema iris than there is in acute and subacute pemphigus; the latter is often a serious or fatal malady, the skin-blebs being but a local manifestation of some more serious

systemic infection the nature of which is ill defined: it is often pyrexial (*Fig. 112*, p. 127). The skin eruption is characteristic, and there is often eosinophilia.

15. **Rat-bite Fever** (see p. 740).

16. **Trench Fever.** This disease was responsible for very large numbers of cases of P.U.O. (pyrexia of unknown origin) during the Great War, and its nature remained a puzzle for a long time until it was shown to be a malady due to a living virus inoculated

Fig. 567.—Four-hourly temperature chart in a case of fatal head injury without fracture of the skull. Post-mortem, there was diffuse infiltrating subarachnoid hæmorrhage, both over the vertex and at the base around the pons Varolii and the medulla oblongata.

by scratching the excreta of infected lice into the skin. Unrecognized as a rule in civil practice, it would be difficult to believe that it does not exist, at any rate amongst the uncleanly. It begins as an acute illness very like influenza, with headache, chill, pyrexia, coated tongue, pink conjunctivæ, loss of appetite, sore throat, frequency of micturition, pain in the back, often abdominal pain which may be acute enough to suggest appendicitis, sometimes erythema, and there is generally slight enlargement of the spleen similar to that of typhoid fever. The initial fever lasts a few days or a week, at the end of which time the worst symptoms subside, but with persistence of various pains and aches, particularly pains in the legs ('shin-pains'), myalgia of the back, and headache. In a few days or a week later there is a relapse of pyrexia, and there may be five or six such relapses, each of short duration, every five, six, or seven days until the chronic stage of the malady is reached: in this there is no special periodicity in the exacerbations, but for months or years the patient is liable to recrudescences of aches and pains and pyrexia without obvious cause, and all this time there is debility, liability to palpitations, tachycardia, and other functional heart symptoms, and the patient, though fit when he first gets up, finds himself fagged out before he is half through his day.

The diagnosis of the chronic cases is extremely difficult because there are no pathognomonic signs and no laboratory tests: there is liability to regard the individual as merely neurasthenic, work-shy, or malingering: but there is no doubt about the reality

Fig. 568.—A morning and evening temperature chart extending over eight weeks in a typical case of trench fever. It shows the initial influenza-like pyrexia of three or four days; the slight relapse before the primary attack has quite passed; and then the recurrent relapses of brief duration extending over weeks at intervals of something less than a week.

of the symptoms in known cases, and it seems probable that instances occur in civil life without their being recognized, because the condition is not thought of. *Fig. 568* is from a case exhibiting the initial pyrexia and several mild relapses; the latter are often of

quite brief duration, and may be missed if the thermometer is not used four-hourly, though the chart is reproduced as though taken morning and evening only.

17. The Persistent Slight Pyrexias of Children. These are often most difficult to assign a cause for: tuberculosis in internal lymph glands is likely to be suspected, but it may be difficult either to establish or to exclude it. Coli bacilluria has to be thought of and tested for; chronic tonsillar infection or a latent gumboil are other common causes. The condition is discussed below, under PYREXIA WITHOUT OBVIOUS CAUSE.

18. Functional Pyrexia. Some patients run a low form of continued pyrexia without any apparent reason for it and without any apparent ill health: they may contend that they are absolutely well and fit for games and everything, yet the continued slight pyrexia keeps one anxious lest there be latent disease, particularly tuberculosis or insidious infective endocarditis. Only when such pyrexia has been watched for months without anything dreadful happening can one gain sufficient confidence to neglect it and write it down as 'functional': even then one is seldom happy, for one has no proof that such apparently functional pyrexias have not really a microbial cause. Probably they have, but there is a type of case in which in the end, when no cause shows itself after weeks of watching and all disease that matters seems to be excluded, one is almost driven to label the pyrexia 'functional'. Seldom is one satisfied in doing so, however, even though one concludes that it is better to desist from using the thermometer and take one's guidance rather from the look of the patient and his appetite than from the chart.

There is quite another type of functional pyrexia in which, without ill health, the thermometer records enormous rises even when fraud seems to be quite excluded—temperatures of 110° or over, for example: these may continue for a long time, and they do not seem to matter: they are discussed in the article on HYPERTHYREXIA (p. 390).

19. Fictitious Pyrexia produced by Malingerers. From time to time one meets with cases in which illness is simulated by a patient who deliberately fakes his or her thermometric records by one or other of various tricks, such as dipping the bulb in a cup of tea, holding it against a hot-water bottle, or rubbing it violently against the blankets. It is said that some have the art of squeezing the bulb between the fingers or between the teeth with just sufficient force to record pyrexia, but without breaking the glass: such a trick must require much more skill than do the hot-tea or hot-water-bottle schemes: but in any case there are cases in which one may be deceived into suspecting some more or less serious pyrexial malady when the patient is merely fraudulent. Hysterical girls may do these things when wishing to create interest in themselves, or malingerers when they do not wish to be discharged to work. The diagnosis depends on suspecting the possibility and then taking the temperatures oneself.

Herbert French.

PYREXIA WITHOUT OBVIOUS CAUSE.—Conditions that produce pyrexia of some duration are discussed in the preceding article, but on the assumption that the cause was ultimately discovered: there remain cases in which, for the time being at any rate, the nature of the disturbances in the temperature chart is obscure, and these merit separate discussion up to the point at which they can be relegated to states mentioned in the above article on PYREXIA, PROLONGED.

I. PYREXIA IN CHILDREN.

The heat-regulating mechanism, like other nervous functions, takes time for its stable and complete development, and it is apt to be upset in children by causes that would not produce pyrexia in an adult: hence transient, irregular, or recurrent rises of temperature in a child may often be of but little significance. *Excitement* is apt to produce transient pyrexia in this way, especially in a nervous child: the effect of visiting day at a hospital in this respect is familiar to all. A bout of *bad temper*, *coughing*, or *crying* may have a similar result: and so may any *upset of the digestion* without need to suppose that there has been any microbial infection.

Nevertheless, if such rises of temperature, even in a child, should prove otherwise than transient and satisfactorily attributable to some known nervous upset, it is unsafe to regard them as purely trivial without making a thorough examination, and there are three things in particular that need to be borne specially in mind if they are not to be

overlooked, these being: (1) *Coli bacilluria*; (2) *Subacute or chronic tonsillitis, often with adenoids*; (3) *Tuberculous bronchial, mediastinal, or mesenteric lymphatic glands*.

1. **Coli Bacilluria** is very apt to be overlooked in a child, for there may be no symptoms attracting special attention to the bladder or kidneys; there may be nothing but pyrexia of obscure origin and perhaps poor general health. Tuberculosis may be simulated. One hesitates at first to obtain a catheter specimen of urine for culture, and may content oneself with having a urine sample examined microscopically; if there are leucocytes present in excess, perhaps with just a haze of albumin, the diagnosis is likely, though it entails culture of a catheter specimen to clinch it.

2. **Tonsillitis and Adenoids** seem to be increasingly common causes for pyrexial ill health in children; and removal of tonsils and adenoids seems to have become necessary in far more cases than of yore; that they are often a source of infection of pyrexial type is familiar, and if they seem to be persistently diseased in a child who is unfit without any other cause for the unfitness being discovered, cessation of both illness and pyrexia after their removal would be the proof that they had been the cause.

3. **Tuberculous Bronchial, Mediastinal, or Mesenteric Lymphatic Glands** may exist in children who have no symptoms at all. Quite large caseous bronchial glands are often found post mortem unexpectedly in seemingly healthy children killed in accidents; cretaceous glands in the abdomens of adults result from healing of tuberculous lesions that have often existed unknown in earlier life; on the other hand, it is from tuberculous mesenteric glands that tuberculous peritonitis develops, and previous to the true nature of the trouble becoming obvious, the glandular lesions may produce no other clinical evidence than bouts of pyrexia of obscure origin. Possibly there may be vague abdominal pains at times, perhaps simulating appendicitis or coli bacilluria; or, in the case of the corresponding bronchial or mediastinal glands, cough without abnormal physical signs. In a great many such cases the correct diagnosis remains one of guesswork only; though there may be a direct guide from the existence of knotty or even larger lymphatic glands down each side of the neck; or from skiagraphic evidence of definitely enlarged glands in the chest (*Fig. 155, p. 187*); or from a strongly positive von Pirquet's cutaneous tuberculin reaction (*p. 932*); or, very occasionally, from being able to palpate definitely swollen intra-abdominal glands through the abdominal wall or per rectum. Most of such cases have derived their infection from unboiled cow's milk, and inquiries as to the source of the milk supply may sometimes afford collateral evidence as to the probability or otherwise of the glandular infection existing; in a considerable proportion of the cases, however, the condition is guessed at rather than diagnosed, though it is far from an uncommon cause of pyrexia of obscure origin.

II. PYREXIA IN ADULTS.

Pyrexia in adults without obvious cause may have the same kinds of causes as in children, but it is less likely to be purely nervous. One meets with cases in which slight pyrexia continuing for a long time baffles diagnosis until ultimately one becomes inclined to attribute it to nervous peculiarity, but this is always unsatisfactory, and frequently erroneous; unsuspected infection somewhere—septic or tuberculous—is generally at the root of such cases; when pyrexia is purely functional it tends to run riot and become extreme (see *HYPERPYREXIA, p. 390*).

One may subdivide the types of pyrexia in adults that puzzle one into three main groups, namely: (1) *Transient or short pyrexia*; (2) *Continued pyrexia of low degree*; (3) *Continued pyrexia of more than low degree*.

1. **Transient or Short Pyrexia.** There is a great tendency to call almost any illness *influenza* when the chief phenomena are pyrexia of a few days' duration, together with the accompaniments of fever—coated tongue, distaste for food, malaise, aching all over, perspiration, high-coloured urine—yet without objective evidence of disease in any one organ; but it is seldom possible, except in times of epidemic, to establish such diagnosis with certainty. Virtually 'influenza' has come to mean almost any transient pyrexial illness for which no other name can be found. When the attack is very short indeed the term *febricula* is used sometimes instead, and perhaps one or other of these labels serves its purpose well enough if one does not delude oneself into the belief that one has really diagnosed the case. Some are doubtless truly influenza; most are something else. If

the illness passes off completely and no further ill health results, it does not matter, but if there should be recurrences it is more than likely that some more definite cause is at work notably either *tuberculosis* or something *septic*. Patients who get influenza five times a year often prove to have phthisis, each 'influenzal' attack being one of the 'pousses évolutives' of the lung disease. Sputum tests and skiagraphy of the chest should be resorted to. Alternatively there may be some form of insidious sepsis somewhere, possibly mild in degree yet undermining to the health, in connection with teeth, tonsils, gall-bladder, kidney, or some other part as discussed below.

2. Continued Pyrexia that is not Extreme is often met with, especially perhaps in children, young adults, and women, without any cause being assignable, the condition being put down sometimes to idiosyncrasy or nervousness when really the trouble may be amongst the following :

Pulmonary tuberculosis
Tuberculous internal lymph-glands
Chronic sepsis somewhere, especially in connection with :
Teeth
Tonsils

Nasal sinuses - antral, frontal, ethmoidal, sphenoidal
Bronchial tubes
Gall-bladder - cholecystitis
Kidneys - coli bacilluria
" - streptococco-uria
Bladder - cystitis
Fallopian tubes - pyosalpinx

Uterus - endometritis
Vagina
Vermiform appendix
Colon - intestinal toxæmia
" - colitis
Seminal vesicles - vesiculitis
Heart - infective endocarditis.

The difficulty is to be sure of the exclusion of tubercle first ; and then to differentiate between the various possible sources of chronic sepsis. There may be a septic tooth, for example, or septic tonsils, yet the real source of the trouble may be a cholecystitis, a coli bacilluria, or a pyosalpinx. The whole field may have been examined bacteriologically, and yet it may be most difficult to interpret the relative importance of the bacteria or cocci found. Organisms may be recovered from the urine, yet there may be no trouble in the kidneys themselves - the microbes may have been absorbed from a septic antrum, for example, and merely eliminated from the blood-stream by perfectly healthy kidneys. Blood cultures are seldom positive in these milder types of cases, but they should be carried out, for if positive they are most helpful in clinching the organism that is causal. It may

FIG. 569. -Temperature chart from a case of lymphatic leukaemia in a woman, age 50.

otherwise require the greatest clinical and bacteriological acumen to sift the laboratory evidence that accumulates, and no simple rules can be laid down for guidance. Perhaps it is wise always to suspect the commonest sites of infection to be the likeliest, and therefore, after tubercle has been excluded as far as feasible, the teeth and the tonsils and the nasal sinuses should be suspected next ; guided by X-ray examination of the teeth, and especially by the existence of evidence of apical infection (Figs. 61-63, p. 43) rather than of mere pyorrhœa or of periodontitis, dental extractions may be resorted to in the hope that the pyrexia will cease and the diagnosis be verified as the result of treatment ; but in

many cases it may take a great deal of patient thought and trial before the septic source of the illness is finally settled.

Infective endocarditis, very dubious sometimes in its earlier weeks or months, finally becomes obvious from the progress of the disease, the development of heart murmurs, enlargement of the spleen, and other signs detailed on p. 16.

Fig. 579. Temperature chart from a case of dental sepsis simulating typhoid fever in a male, age 33, showing prolonged pyrexia which, in view of the relatively slow pulse-rate and the absence of abnormal physical signs, led to a diagnosis of typhoid fever. The patient had complained of a sore place on his gum early in the malady, but little attention was paid to this; ultimately a gumboil developed, the tooth was extracted, and the pyrexia forthwith ceased. The Widal reaction was negative throughout.

Trench fever is discussed on p. 710; and *malaria* on p. 37; the latter, *dysentery*, and other tropical causes of recurrent or continued pyrexia, will be suggested by the geographical details of the past history; all these may produce pyrexia of a type that may be long and indefinite.

3. Continued Pyrexia that may be Pronounced yet of Obscure Origin may sometimes prove baffling, especially when it is observed in patients who seem visceraally sound and who may even resent being regarded as ill. When ill health is associated with the pyrexia the search for the cause is likely to be more meticulous, and the reason for the continued temperature the more likely to be discovered in the end.

Some guidance may be afforded by the general character of the chart—the periodicity of *Pel-Ebstein's disease*, for instance (*Fig. 566*, p. 708), or of *rat-bite fever* (*Fig. 579*, p. 740), or of *relapsing fever* (*Fig. 48*, p. 36): or the relatively slow pulse-rate in *typhoid fever* (p. 784) or *paratyphoid A*, *paratyphoid B*, or *paratyphoid C*. Serum reactions may afford positive evidence of the typhoid group of fevers, or of *Malta fever* (p. 691), though absence of a positive Widal's test does not exclude typhoid or paratyphoid.

Polymorphonuclear leucocytosis may point to the existence of unsuspected pus, to the exclusion of typhoid fever or malaria, in both of which there is leucopenia or at least no leucocytosis.

Lumbar puncture may be required in the diagnosis or exclusion of meningococcal meningitis, or other meningitic disease.

Blood counts (see pp. 30-35) may be needed to exclude *lymphatic* or *splénomedullary leukaemia*, in each of which quite considerable pyrexia may occur either continuously or at intervals (*Fig. 569*, and *Fig. 47*, p. 34): or *pernicious anaemia* (*Fig. 565*, p. 707).

Blood cultures may occasionally afford the diagnosis in certain cases of *subacute septicæmia*, or of *infective endocarditis* of long duration (*Fig. 65*, p. 46).

Urine cultures may detect the existence of unsuspected *coli bacilluria* (*Fig. 448*, p. 560).

Examination per rectum or per vaginam may detect latent infection in the form, for instance, of *pyosalpinx*, *prostatitis* or *prostatic abscess*, *diseased seminal vesicles*.

Careful attention to the patient's story as to where there is or has been an ache or a pain may lead to the discovery of *cholecystitis*, or *antral empyema*, or *frontal sinus disease*, or other similar septic focus that may be missed if the story is not gone into with care. *Fig. 570* is from a case in which the diagnosis seemed to be typhoid fever until a tooth with a gumboil was removed, the patient having complained of a sore place on his gum at the beginning, though this part of his story had received too scanty attention at the time.

Skiagrams of the teeth may be needed to exclude *apical dental infection* (*Figs. 61-63*, p. 43) capable of producing considerable pyrexia.

Special investigation of the *tonsils* may be needed to exclude persistent sepsis in the lower pole of one or both as being responsible for continued pyrexia.

Tubercle, whether of the lungs or of internal lymphatic glands, will sometimes be very difficult of either diagnosis or exclusion: a skiagram of the chest should not be omitted, but quite frequently it becomes a matter of guesswork rather than of diagnosis as between the existence or the absence of ill-defined tuberculosis when continued pyrexia is a prominent feature in any particular case. Much clinical acumen is called for in being even approximately near the mark in giving an opinion.

Finally, it is noteworthy that continued pyrexia may be a feature of hepatic lesions that are not essentially septic, that is to say, apart from *cholecystitis*, *suppurative cholangitis*, or *suppurative pylephlebitis*: one meets with continued pyrexia in *cirrhosis of the liver* (*Fig. 66*, p. 47) even when the patient may be well enough to work and live as usual; and it may be even more marked when there is *secondary carcinoma in the liver* (*Fig. 323*, p. 408), the primary growth possibly producing no symptoms at all. *Herbert French.*

PYROSIS. (See HEARTBURN, p. 376.)

PYURIA. Pus appears in the urine in all suppurative conditions affecting the urinary tract and occasionally from the rupture of an extra-urinary abscess into the urinary apparatus. It may be present in large or in microscopic quantities: when in bulk it forms a thick, greyish, tenacious sediment, which must be distinguished from phosphates and from urates: urates, though they may be colourless, are generally of a pinkish or even brick-red colour, owing to the uroerythrin they carry down with them, and they clear up on warming the specimen back to body temperature: phosphates clear upon the addition of acetic acid: whereas pus will remain unaltered by either test.

In alkaline urine pus cells tend to run together into a dense viscid deposit, leaving

the upper layers of the urine slightly turbid. Microscopically each pus cell is multinuclear, rounded, and about twice the size of a red blood-disc. The contents are granular, but the addition of acid clears the cell and makes the nucleus stand out distinctly. Urine containing pus always contains at least traces of albumin, and frequently epithelial cells from some part of the urinary tract. If the specimen containing pus be shaken gently with ozonic ether, a slight effervescence will be produced, or if mixed with liquor potassæ, aropy precipitation occurs.

The following is a classified list of the causes of pyuria :—

I. From Diseases of the Urinary Organs.—

- | | | |
|-------------------|--------------------------|-----------------------|
| 1. <i>Renal</i> : | 2. <i>Ureteric</i> :— | Bilharzia hematobia |
| Pyelitis | Calculus | 4. <i>Prostatic</i> : |
| Colibacilluria | 3. <i>Vesical</i> :— | Prostatitis, acute or |
| Pyelonephritis | Cystitis | chronic |
| Renal abscess | Tuberculosis | Prostatic abscess |
| Pyonephrosis | Calculus | Calculus |
| Tuberculosis | Ulcer simple, epithelio- | 5. <i>Urethral</i> : |
| Calculus | matous | Urethritis - gonor- |
| Carcinoma | Tumour—sloughing pa- | rheal, septic, gouty |
| Sarcoma | pilloma, villus-covered | Stricture. |
| Hypernephroma | carcinoma | |

II. From Diseases Outside the Urinary Organs.—

- | | |
|-------------------------------------|---------------------------------------|
| Leucorrhœa | Iliac or pelvic abscess |
| Balanitis with phimosis | Abscess due to colonic diverticulitis |
| From the extension of inflammatory | Psoas abscess |
| processes to the bladder, or the | Pyosalpinx |
| rupture into the bladder or urethra | Carcinoma of the uterus, rectum, |
| of an abscess such as : | cecum, sigmoid, or pelvic colon |
| Prostatic abscess | Ulceration of the small intestine - |
| Appendicular abscess | tuberculous or dysenteric. |

It is impossible to determine the lesion producing pus in the urine simply by the examination of the latter. Due consideration must be given to the history and the other symptoms of any case, and particular care be taken not to lay too much emphasis upon any symptom which may point to a vesical lesion when in reality the trouble is in the kidney. This is perhaps most likely to occur in a hematogenous infection of the kidney by micro-organisms, in which increased frequency of micturition is a marked symptom, whilst the bladder may remain free from disease. Occasionally, after pus has been present continuously in the urine for some time, it may disappear entirely, the change being accompanied by increase of pain in the side, by an elevation of temperature, or enlargement of the kidney in a case of pyonephrosis when the obstruction to the flow of urine from that side has become temporarily complete. Very little help is derived from the character of epithelial cells accompanying pus in the urine. The shapes of the cells of the renal pelvis, ureter, and deeper layers of the bladder are so much alike that it is usually impossible to differentiate them.

Some assistance in the determination of the origin of the pus in the urine may be gained by instrumental examination :

By Catheter.—If a catheter be passed and the bladder washed out with clear solution of boric acid, it will be found that the medium is soon rendered clear if the pyuria is of renal origin, but that it is much more difficult to obtain a perfectly clear medium if the bladder is the seat of the suppuration. If the medium is cleared quickly, but yet, after some ten minutes' retention in the bladder it is again found to be turbid, the pus is almost certainly descending from the kidney.

The Cystoscope.—Much more certain evidence is gained by a careful cystoscopic examination. By this means it can be determined in the great majority of cases if the bladder is infected or if any ulceration is present. In a few cases the bladder may be so affected that only a small dilatation is allowed, or bleeding is produced so easily that cystoscopy is rendered difficult ; in these cases there will be little need for an inspection of the bladder. If the bladder be found to be normal, evidence of a suppurative lesion in the kidney may be obtained from the appearance of the ureteric orifices or by the variations in the character of the urinary efflux from them. Instead of the normal forcible

flow of clear urine from each orifice, mixing with the medium in the bladder in a characteristic swirl, urine containing pus may be seen emitted, appearing in the field as a small smoky puff from the orifice (*Fig. 571*): pieces of mucus may be seen to pass from the orifice, or the turbid urine may be seen to leave the orifice in a gentle trickle instead of a jet if the renal secreting function is impaired or if renal dilatation is present.

Fig. 571. Paradoxic urine issuing from the ureter.

Fig. 572. Congestion around a ureteric orifice in calculous pyelitis.

Fig. 573. The retracted ureter common with descending renal tuberculosis.

Fig. 574. Tuberculous ulceration around the ureteric orifice in descending renal tuberculosis.

(From sketches kindly lent by Dr. C. F. Walters.)

Apart from the alterations in the urinary efflux from an orifice, the actual appearance of the orifice may show changes which indicate renal disease. Thus, in pyelitis, the margins of the orifice are slightly oedematous and congested, and appear to pout into the bladder (*Fig. 572*): the mucous membrane of the bladder, immediately below and internal to the orifice, is frequently congested or granular from the effect of the altered urinary flow upon it. If the renal pelvis and ureter are dilated, the orifice is usually elongated and patulous, whilst in tubercle or in diseases in which the ureter is thickened, the whole ureteric orifice is drawn upwards and outwards from its normal situation (*Fig. 573*), and is seen at the apex of a conical retracted area in the bladder base.

I. PYURIA CAUSED BY DISEASES OF THE URINARY ORGANS.

Renal Disease. *Diseases of inflammatory origin.*

Pyelitis and *pyelonephritis* may arise as an ascending infection from the lower urinary tract, especially when there is some obstruction to the normal passage of urine. Thus it is common in cases of prostatic enlargement and stricture. When cystitis is present, it is

usually bilateral, although one kidney may show much more advanced disease than the other. Any growth or lesion in the bladder which is accompanied by suppurative infection, and which involves the ureteric orifice, such as vesical epithelioma, or the direct involvement of one or both ureters in the spread of uterine cancer, may set up pyelitis in the kidney, the infection ascending either by the ureter or by the peri-ureteric lymphatics. In this group of cases the primary cause of the disease has usually advanced to a sufficiently late stage to be obvious, and the symptoms of suppurative ascending infection of the renal pelvis or renal tissues are usually overshadowed by the symptoms of the disease causing the obstruction. Aching in the loin, rigors or raised temperature, tenderness on deep palpation in the renal area or actual renal enlargement, thirst, and loss of appetite are usually indicative of renal infection. The urine is often increased in quantity, of low specific gravity, and the daily excretion of solids is lessened; the skin is dry and harsh and the tongue dry. In cases of pyelonephritis secondary to some form of urinary obstruction, an estimation of the urea content in the blood will show this to be raised above the normal maximum of 40 mgrm. per 100 c.c.

Pyelitis and pyelonephritis may also arise as an infection of the kidney apart from any other disease in the genito-urinary organs. Infection is conveyed to the kidney by the blood-stream (haematogenous form), and is not uncommon in acute fevers, or with mild forms of suppuration in other parts of the body, or in association with pregnancy. In the less acute forms a pyelitis may result, as in typhoid fever, but in most cases the haematogenous infection produces first a suppurative process in the renal parenchyma, from which infection spreads to the calices and pelvis. This form of disease is due most frequently to the colon bacillus in association with affections of the intestinal canal (*colibacilluria*), less frequently to the staphylococcus, streptococcus, pneumococcus, typhoid bacillus, *Bacillus pyocyaneus*, or *Bacillus proteus*. The renal pyelitis which ensues when a calculus has ulcerated into the renal pelvis is a haematogenous infection.

Acute haematogenous infection of the renal pelvis without involvement of the renal parenchyma usually begins with slight rigors, tenderness in the loin, and increased frequency of micturition. The urine is faintly turbid and opalescent, does not settle to a pronounced sediment, but remains of a sheeny appearance. It contains numerous bacteria, a little pus, and a little albumin; the causal organism is determined by bacteriological cultivation of a catheter specimen, obtained aseptically without the use of antiseptics. There is often marked pyrexia (*Fig. 448*, p. 560). When the infection first attacks the renal parenchyma as well as the pelvis the symptoms are more severe, and the patient may become uræmic rapidly. In the less acute cases small foci of suppuration occur, which coalesce to form an *abscess*, with the general symptoms of suppuration. Renal abscess may also result from injury when an effusion of blood in the renal tissues becomes infected by pyogenic micro-organisms, or by the breaking down of a renal infarct.

Pyonephrosis—or dilatation of the pelvis and calices of the kidney with pus and urine—is caused when suppuration has occurred in a kidney which is at the same time subjected to some form of obstruction to the normal exit of the urine. Pyonephrosis is caused most commonly by renal calculus or tuberculosis, but is by no means uncommon with a chronic cystitis, complicating urinary obstruction from an enlarged prostate or stricture. Carcinomatous ulceration affecting a ureteric orifice, either primary in the bladder or by direct extension of uterine cancer, is also a comparatively common cause of pyonephrosis. In contradistinction to suppurative pyelonephritis, the symptoms of pyonephrosis are less severe; at first they are those of the obstructive lesion causing the disease, to which are added the general symptoms of suppuration. Pyonephrosis causes a renal tumour of variable size, a decrease being associated with the discharge of a larger amount of pus in the urine. In pyonephrosis due to calculous disease the urine may contain a large amount of pus, but there may be no lumbar pain suggesting a renal stone. In these cases a large calculus will usually be found in the renal pelvis, and will be shown on X-ray examination (*Figs. 354–356*, p. 440, 441).

The urine in suppurative disease of the kidney and its pelvis requires careful examination. It may be normal with a localized cortical renal abscess or with closed pyonephrosis; in all other lesions it contains pus and micro-organisms. If the pus-cells are found in the form of casts of the renal tubules, infection of the renal parenchyma is present, whilst in this latter the albumin in the urine is in excess of that due to the pus present. Polyuria,

with a diminution of the total solids of the urine in a daily examination, is commonly present in inflammatory lesions of the renal tissue.

Renal Tuberculosis.—The miliary form of tuberculosis occurs in children as part of a general dissemination of tubercle, and causes no urinary symptoms. The kidney is, however, attacked not infrequently by primary tuberculous infection, beginning as a unilateral deposit of small tuberculous nodules. These enlarge and coalesce to form a caseating area, which eventually opens into the renal pelvis by direct ulceration of a calix: the lining membrane of the renal pelvis and ureter become infected with tubercle subsequently and thickened by submucous infiltration. At first, before ulceration into the renal pelvis has occurred, the symptoms of the disease are very slight; there may be aching in the loin and slight albuminuria, but as soon as the renal pelvis is involved more marked symptoms occur—persistent pyuria, lumbar aching, increased frequency of micturition, and polyuria. The urine is pale, of low specific gravity, and of opalescent turbidity: by careful examination after centrifuging, the tubercle bacillus is usually found. A small amount of blood is generally present. The increased frequency of micturition occurs before any descending vesical infection has occurred, and this symptom, accompanied by pyuria, has frequently given rise to a diagnosis of vesical disease. The occurrence in a young adult of persistent pyuria which is not due to gonorrhœa, injury, or stone, should always be looked upon with grave suspicion, and a careful search made for the tubercle bacillus: should this not be found by the microscope, diagnosis by inoculation of some of the urinary deposit into a guinea-pig should be resorted to. A careful cystoscopic examination of the bladder should also be made, when early vesical tuberculosis may be seen (*Fig. 574*, p. 717), or the characteristic changes in the ureteric orifice may show the presence of renal infection (*Fig. 573*, p. 717). By digital examination per rectum or per vaginam the lower end of the ureter may be felt to be thickened and rigid in renal tuberculosis.

Renal tuberculosis is often confounded with renal stone, and the colic which is usually associated with stone may be present in tuberculosis if a piece of caseous debris be passed down the ureter. A skiagraphic shadow of a calculus shows well-defined margins (*Figs. 354–356*, pp. 440, 441), whereas a tuberculous focus in the kidney may give rise to a faint, blurred, indistinct shadow in the renal area (*Fig. 287*, p. 352). The presence of tubercle bacilli will, however, determine the existence of tuberculosis, whilst tuberculous lesions elsewhere in the body, most frequently in the testes, prostate, or vesiculæ seminales, may also serve to confirm the diagnosis.

The symptoms of *renal calculus* vary with the position of the stone and the changes that have taken place in the kidney in consequence of its presence. It may be situated in the renal parenchyma, and cause no symptoms beyond lumbar aching; or in the renal pelvis, when, if movable, it may cause acute renal colic, due either to the attempted passage of the stone by the pelvic outlet or to the increased intrarenal pressure from blockage of the ureter. So long as the kidney remains aseptic the urine contains but traces of albumin, or none, and only microscopic quantities of blood: but if it becomes infected with micro-organisms pyelitis, pyelonephritis, or pyonephrosis may result, with their attendant symptoms. Pus only occurs in the urine in a case of renal stone when infection of the kidney has occurred.

Ureteric Calculus. A small renal calculus may become impacted during its passage along the ureter, and many cause some difficulty in diagnosis. The usual situations of the obstructed calculus are in the upper few inches of the ureter, at the pelvic brim, or at the vesical end of the tube: in most cases the previous history of renal colic and symptoms of renal stone will be sufficient to indicate its partial ureteric descent. A calculus may, however, be present in the upper end of the ureter or at the pelvic brim, and give very few symptoms beyond a fixed pain in the course of the ureter: in the latter situation it has frequently been mistaken for ovarian pain or for chronic appendicitis. If the stone blocks the ureter completely, the kidney of the same side—in the absence of septic infection—becomes functionless and atrophies; but if the calculus occludes the lumen of the tube only partially renal distention will occur, with resulting hydro- or pyonephrosis. If, however, the calculus becomes impacted in the vesical segment of the ureter a train of symptoms occurs simulating vesical stone or vesical tuberculosis—namely, increased frequency of micturition, penile pain following micturition, and often a small amount of

blood and pus in the urine, in addition to the aching pain in the loin. A ureteric calculus impacted in this situation may often be felt in the ureter upon rectal or vaginal examination: it may be demonstrated by the X rays (*Fig. 447*, p. 558): whilst the changes seen around the ureteric orifice, and the absence of a vesical lesion on cystoscopic examination, will confirm the diagnosis.

Vesical Diseases. Pyuria may be met with in any lesion of the bladder which is associated with inflammatory changes. The fact that urine is retained in the bladder renders the latter more liable to septic infection, so that cystitis is common with urethral stricture or prostatic obstruction. Any ulceration of the bladder, tuberculous or malignant, is also accompanied by inflammatory changes, when pus will be present in the urine.

Cystitis may be acute or chronic, and the essential factor of either form is the infection of the bladder by some micro-organism: any agent which produces either congestion of the bladder or retention of urine acts as a predisposing cause.

With *acute cystitis* the mucous membrane of the bladder becomes redematous and highly congested, and epithelial desquamation and formation of pus follow. Haemorrhage may occur from the congested mucosa, or small abscesses develop in it and rupture into the bladder, to leave small areas of ulceration. In severe cases patches of the mucous membrane may become gangrenous. The symptoms of acute cystitis are usually distinctive: frequent and painful micturition, elevation of temperature, pain in the perineum and suprapubic area, with the presence of pus and blood in the urine, which is commonly of an acid reaction. Usually, some distinct cause for the onset of acute cystitis is apparent, such as some form of acute urethritis or of previous instrumentation, and there is little difficulty in the diagnosis. The same symptoms are, however, produced by an acute inflammation of the prostate which, in nearly all cases, is preceded by acute urethritis: the presence of swelling of the gland, and acute pain on rectal palpation, will determine the existence of prostatic inflammation.

Chronic cystitis may succeed acute. The symptoms are less marked, but increased frequency of micturition is always present. The urine is alkaline, contains pus and mucus, and the disease is commonly associated with some form of urinary obstruction, or with retention or incontinence due to some nervous disease, such as *tabes dorsalis* or transverse myelitis. The association of pyuria and increased frequency of micturition, which is present in chronic cystitis, must be distinguished carefully from that due to pyelitis or pyelonephritis, for increased frequency of micturition may be present without any vesical infection. In renal pyelitis the urine is usually acid in reaction, pale in colour, and shows a general turbidity, with little inclination towards a deposit at the bottom of a specimen. The urine of chronic cystitis is alkaline, and rapidly deposits a greyish sediment of pus. In pyelitis and pyelonephritis, the urine contains more albumin than the pus would account for, and on microscopic examination renal or pus casts are frequently found: whereas in cystitis the albumin is less, and vesical cellular elements are present, without casts unless the kidneys are affected also. Further evidence may be obtained by the use of the cystoscope. In cystitis the bladder wall is trabeculated and the mucous membrane thickened: it has lost the normal iridescent appearance, and the vessels of the mucous membrane are obscured. With pyelitis, the bladder wall is normal, but the ureteric orifice of the affected side shows thickened or pouting lips and a slightly raised area of thickened mucous membrane, whilst the urine flowing from the orifice may be seen to be turbid or to contain small particles of mucopus.

Chronic cystitis may be simulated by an inflammation of the posterior urethra. In such a case there is almost always a history of urethral infection, and the diagnosis can be made by urethral irrigation. The patient is directed to retain his urine for some three hours, and after irrigating the anterior urethra as far as the compressor muscle with sterile water or boric acid lotion, the urine is passed into two glasses. With posterior urethritis, the urine in the first specimen will contain shreds of mucopus, whilst that of the second specimen is clear: with cystitis, the second specimen will be as turbid as, or even more turbid than, the first.

Tuberculous cystitis occurs usually in young adults, and is almost always secondary to tuberculous disease of a kidney or of the generative organs. The characteristic symptoms are increased frequency of micturition during both day and night, pyuria, with pricking

pain in the glans penis at the end of micturition, and the appearance of a few drops of blood in the last drops of urine. The same symptoms are often present with vesical calculus and with vesical epithelioma when ulceration has taken place. Vesical calculus is usually present in older patients, and during the early part of the illness, before cystitis has set in, the calculus only gives rise to penile pain and desire to micturate during movement. When cystitis supervenes, the frequency of micturition will be marked during both day and night. Vesical epithelioma also occurs in older patients, and when ulcerated may cause hæmaturia: frequently the diagnosis may be made by palpation per rectum of an indurated area in the bladder base, or of some enlarged glands in the pelvic lymphatic space. Tuberculous cystitis in the early stages, when the disease is characterized by the deposition of greyish tubercles in the submucous coat of the bladder, may give rise to increased frequency of micturition without other symptoms, but in the progressive advance of the disease the tubercles enlarge, coalesce, and ulcerate on the surface, by which time pus and blood will be present in the urine, tubercle bacilli should be found, and the patient may be unable to hold urine for more than twenty minutes or half an hour. It may be taken as a general rule that in any patient of young adult life with increased frequency of micturition and pyuria, a careful search should be made for tubercle bacilli in the urine, and for other tuberculous lesions, especially in the testes, prostate, or vesiculae seminales.

Tuberculous cystitis is much less often a primary disease than secondary to other lesions in the genito-urinary apparatus—most commonly to tuberculous disease of one kidney, when, after the primary focus has ruptured into the renal pelvis, the lining membranes of the latter, of the ureter, and of the bladder become affected successively. It may be due to tuberculous disease of the testicle, via the vas deferens, seminal vesicle, and prostate: occasionally a prostatic focus ulcerates directly into the bladder. With renal disease, persistent pyuria, increased frequency of micturition, and penile pain at the termination of urination may be present before the bladder shows any sign of disease: blood is usually present in small quantity in the urine, but its amount is not so definitely greater in the urine passed at the end of micturition as is the case in vesical disease. In renal tuberculosis there may be tenderness in the loins, the kidney is usually enlarged, and the lower end of the ureter can be felt distinctly thickened upon rectal or vaginal examination. The two conditions can usually be distinguished by careful cystoscopic examination. In vesical tuberculosis the deposition of submucous tubercles, together with the shallow ulceration in the bladder mucous membrane, may be seen (*Fig. 574*, p. 717), whilst in renal tuberculosis changes may be seen in the ureteric orifice of the affected side (*Fig. 573*, p. 717): at first the orifice becomes thickened, oedematous, and slightly patulous: but later it is rigid and patent, or drawn up by the shortening of the ureter to occupy a position above and outside the normal situation in the trigonal area of the bladder, or drawn up to the apex of a conical retraction of the bladder base. When tuberculous cystitis is secondary to lesions in the testes, prostate, or vesicles, the disease commonly begins in the epididymis of one side, and spreads to the vesicle or prostate, whence a focus may ulcerate directly into the bladder. The patient will first notice increased frequency of micturition and vesical pain, followed by an attack of hæmaturia when actual ulceration into the bladder base occurs: the formation of a tuberculous ulcer in the bladder leads to pyuria and the other symptoms mentioned above. This sequence is by no means uncommon: the history of testicular disease and the evidence obtained by rectal examination will help to indicate the nature of the condition.

Vesical calculus may give rise to pyuria when it is accompanied by cystitis, but may be present a long time before any inflammatory infection occurs. When cystitis is present the urine shows no features which will distinguish it from that of patients suffering from some other form of cystitis, except that there may be a constant presence of crystals, or an increased amount of blood after exercise. The constant symptoms of vesical calculus are vesical irritability during the day time, penile pain after micturition, and hæmaturia, especially after any exercise. If a calculus in the bladder is suspected, examination by the X rays (*Fig. 294*, p. 355), a sound, or the cystoscope, will reveal it: the cystoscope may detect a stone that is in a diverticulum, partially encysted or lying in the pouch behind an enlarged prostate, where it may easily be overlooked in searching the interior of the bladder with a sound.

Ulceration of the bladder, apart from tuberculosis and epithelioma, may occur as a simple ulcer, consecutive to chronic cystitis, or as the result of injury. A single non-tuberculous ulcer, similar to gastric ulcer, has been described as occurring in young adults in the neighbourhood of the ureteric orifices, causing hæmaturia and painful frequent micturition. Later, the surface of the ulcer may become encrusted with phosphatic material, when the urine contains mucopus, and often small flakes of phosphatic debris from the surface of the ulcer. This single ulcer is rare, and can be diagnosed only by the use of the cystoscope. Ulceration may also occur in the bladder as a result of severe cystitis, when necrosis has occurred in the mucous membrane. This condition is present occasionally in a case of obstinate cystitis, giving rise to painful and frequent micturition, and may be diagnosed by means of the cystoscope. Both the simple and the consecutive ulcer must be differentiated from tuberculous ulceration of the bladder: in the latter, hæmorrhage is usually slight, and occurs at the termination of micturition; tubercle bacilli may be found in the urine, or other deposits of tubercle found in the epididymis, prostate or seminal vesicles. The cystoscopic appearance of tuberculous disease, and its more generalized distribution in the vesical wall, will afford the strongest evidence in the diagnosis.

Malignant ulceration of the bladder occurs in two distinct forms: (a) The infiltrating epithelioma; (b) The villus-covered carcinoma.

a. The *infiltrating variety* occurs as an ulcer, with raised edges and uneven necrotic surface, usually at the base of the bladder. It is usually met with in men over fifty years of age, causing increased frequency in micturition, pain at the glans penis following micturition, with blood and pus in the urine. The bladder wall in the vicinity of the ulcer is densely infiltrated, and frequently can be felt on digital examination per rectum, whilst at the same time the lymphatic area in the pelvic space may be felt to be thickened, or enlarged glands may be palpated.

b. The *villus-covered carcinoma* of the bladder is not uncommon, and gives rise to irregular profuse hæmorrhages. The tumour is attached to the bladder by a broad pedicle or may be entirely sessile and covered by blunt villi, presenting a coarsely mammillated surface. It occurs in elderly patients, and the tumours are frequently multiple. The surface is often necrotic, giving rise to pyuria. The diagnosis is not difficult, the frequently recurring hæmorrhages in the urine, associated with increased frequency of micturition, pain, and pyuria in an elderly patient, being fairly distinctive. Not uncommonly there is unilateral renal aching from the interference, by the position of the growth, with the flow of urine from one ureteric orifice, so that renal disease may be suspected: but in all cases a careful cystoscopic examination will show the nature of the disease. Difficulty may be experienced in obtaining a satisfactorily clear medium for a cystoscopic view, but in most cases this can be accomplished by gentle manipulations or by the use of a styptic such as adrenalin 1 1000 or silver nitrate 1 1000. Difficulty may be found in distinguishing cystoscopically between a benign papilloma and villus-covered pedunculated carcinoma: but the broad attachment of the latter to the bladder, the stunted villi covering it, and the multiplicity of the tumours, will be signs of malignant disease (*Fig. 288*, p. 354). In rare instances a *benign papilloma* may begin to slough on the surface or may be accompanied by cystitis, when pyuria will be present. A cystoscopic examination will reveal the diagnosis. Microscopical examination of the urinary deposit may show distinctive fragments of new growth: these fragments of growth represent small pieces of the surface of the tumour only, and therefore no opinion can be expressed as to whether the parent growth is innocent or malignant.

Bilharzia hæmatobia may cause pus in the urine in advanced cases. When the small nodules in the submucous tissues (*Fig. 291*, p. 354) of the bladder ulcerate, small fungating masses are found in the bladder. The typical ova in the urine (*Fig. 96*, p. 102), in addition to pus and blood, will be found on microscopical examination of the urinary sediment.

Urethral Causes. Any condition which sets up a purulent urethritis will cause pyuria. If the urethritis is recent or profuse, the local condition will be enough to indicate the diagnosis, but it must be remembered that cystitis may complicate a case of urethritis by direct backward infection. If, in addition to urethral discharge there is increased desire to urinate, suprapubic pain, or hæmaturia, acute cystitis is probably present. The

anterior urethra should be irrigated well with sterile water or boric acid lotion, and the patient then directed to pass urine into two glasses. If the first portion passed contains pus and the second is clear, infection is present in the posterior urethra and not in the bladder, but if both specimens are turbid with pus, cystitis is present.

The onset of acute prostatitis complicating urethritis gives rise to increased desire to micturate, and perineal and suprapubic pain, in addition to pyuria, or may cause retention of urine. Digital examination of the prostate per rectum will show the prostate to be enlarged and very painful.

A small amount of pus may be present in the urine in cases of chronic urethritis which is not sufficient to cause any visible discharge from the meatus. The anterior urethra should be irrigated well, and the urine again passed into two separate glasses, when, if the first washings from the urethra contain pus, there is infection in the anterior urethra; if the first specimen of urine contains pus but the second is clear, there is infection in the posterior urethra; whilst if both contain pus, cystitis is present. In any case of urethral discharge, a bacteriological examination should be made for the organism causing the infection, for it is far from uncommon to find that an apparent gonorrhoeal urethritis is in reality due to staphylococcal infection.

Pyuria is commonly present in cases of stricture of the urethra, from the co-existing urethritis or cystitis.

II. PYURIA CAUSED BY DISEASE OUTSIDE THE URINARY ORGANS.

Pus may be present in the urine, apart from any disease in the urinary apparatus, either by accidental contamination of the urine, or by the direct spread of inflammatory or carcinomatous processes from neighbouring organs to the urethra, the bladder, or more rarely the ureter. In the male, the accumulation of pus behind a *phimosis* may account for pyuria, or in the female a *leucorrhoeal discharge* may contaminate the urine. In the latter case the vulva should be cleansed well with an antiseptic, and a catheter passed to obtain a specimen for examination.

The spread of inflammatory processes, or the actual rupture of an abscess into any part of the urinary tract, will cause pyuria, and may create considerable difficulty in diagnosis. If symptoms pointing to urinary trouble, such as markedly increased frequency of micturition or slight hæmaturia, are followed by the sudden appearance of a quantity of pus in the urine, there is strong probability of the *rupture of an extra-urinary abscess* into the bladder or urethra, provided that the sudden emptying of a renal abscess or a pyonephrosis can be eliminated. Frequently the history of any case will give some indication of the primary trouble, of which the most frequent are prostatic abscess, appendical abscess, pyosalpinx, psoas, iliac, and pelvic abscess, and an abscess around a carcinoma or diverticulitis of the colon.

Prostatic abscess is most frequently a sequela of an acute urethritis which has infected the posterior urethra and caused an acute prostatitis. It may be due to a gonorrhoeal or to a septic venereal infection, or may result from septic instrumentation in the urethra. An acute prostatitis is very prone to result in the formation of an abscess which may rupture into the urethra, bladder, or rectum, unless appropriate surgical measures be undertaken. The onset of acute prostatitis is marked by increasing desire to micturate, pain in the perineum and hypogastric areas, and raised temperature, whilst per rectum the prostate is felt to be uniformly enlarged and very tender. If an abscess results, there may be rigors, pyrexia, and increased difficulty in micturition, even retention of urine, whilst a soft area may be felt in the prostate from the rectal aspect. A prostatic abscess may occur more rarely in connection with a *prostatic calculus*; or may be present in advanced *genito-urinary tuberculosis*, when a prostatic focus may cascade and ulcerate into the trigonal area of the bladder, a condition which is usually accompanied by a sharp attack of hæmaturia. A tuberculous focus in the prostate is commonly a comparatively late feature in the disease, and the presence of nodules in the epididymis or seminal vesicles, or the previous knowledge of vesical tuberculosis, will assist largely in the diagnosis.

Pyuria in Inflammation of the Vermiform Appendix. In the usual position of the appendix the bladder is commonly not affected; but if the appendix passes downwards across the pelvic brim it is not uncommon to find that, should it become inflamed, the

patient complains of frequent and painful micturition. The appendix may be adherent to the bladder, when the latter will show on cystoscopic examination a localized area of acute congestion on the right lateral wall, and both pus and blood may be present in the urine: further, a small abscess may be formed in the adhesions between the appendix and the bladder, ulcerating into the latter and giving rise to pyuria: a ureteral calculus may be simulated, but cystoscopic examination will show a normal ureter, and a small ulcer in the right lateral wall of the bladder surrounded by an area of acute cystitis. The diagnosis of these cases is by no means easy: the situation of the pain is lower in the pelvis than is usual with appendicitis, and the association with urinary symptoms points to vesical disease: but the character of the onset of the trouble, with elevation of temperature and pulse-rate, and right-sided abdominal rigidity, will make one think of alternative acute intra-abdominal lesions. An abscess resulting from appendicular sup-puration may track down into the pelvis and, if unopened, may rupture into the bladder. In these cases there will be the usual history of acute appendicitis, followed by a tumour in the right iliac fossa or pelvic space, with a continuance of pyrexia, or even rigors, which subside on the appearance of a large quantity of pus in the urine.

A *pyosalpinx* may rupture into the bladder or cause cystitis from direct spread of the inflammatory process to the bladder. There will usually be a history of leucorrhœa with constant aching or dragging pains in the lumbosacral region, with more severe attacks of pain and malaise at intervals. The periods may be profuse and associated with more pain than usual, and on vaginal examination a distinct fullness or tumour may be felt in one or both fornices.

Psoas or *iliac abscess* may rupture into the bladder, and a psoas abscess has been known to open into a ureter: but the swelling in the iliac fossa or the inguinal region, together with signs of spinal caries, will point to the condition.

A very rare cause of similar pyuria is *actinomycosis of the cæcum*, which, instead of infiltrating the skin and pointing in the groin externally, may extend into the pelvis and open into the bladder or rectum or both: the diagnosis may be missed entirely unless ray fungi are discovered in the urine as a result of routine and thorough bacteriological investigations. *Actinomycosis of the kidney* is even rarer: it is apt to be mistaken for tuberculosis until the laboratory investigations discover the characteristic ray fungi in the urine.

Carcinoma of the neighbouring organs in the pelvis frequently attacks the bladder by direct spread of the growth. This is most common in carcinoma of the uterine cervix and of the rectum, but may result from cancer of the pelvic colon, sigmoid, or cæcum. The spread of the disease to the bladder occurs late: symptoms of the primary trouble have generally pointed to the diagnosis before pyuria ensues. The implication of the bladder is shown first by an increased desire to pass urine, and by pain during the act: later, when the growth has actually infiltrated the vesical mucous membrane, ulceration into the bladder occurs, with the passage of pus and blood in the urine. If the growth has extended from the uterus or vagina, there may be a leakage of urine into the latter: or if from the rectum or colon, some faeces or flatus may be passed per urethram.

Tuberculous or dysenteric ulcers of the intestine have in some instances become adherent to the bladder wall and caused cystitis by direct spread, or have even perforated into the bladder.

RASHES.—(See ERYTHEMA, p. 275: PAPULES, p. 597: PUSTULES, p. 681: VESICLES, p. 913; etc.)

REACTION OF DEGENERATION. In testing muscles and nerves electrically, two different kinds of current are employed, namely: *faradic*, in which there is a very rapid alternate making and breaking of the current, and *galvanic*, in which the current flows continuously until it is voluntarily interrupted by the operator. The faradic current excites the nerve and muscle continuously all the time it flows: the galvanic current only excites when it is made and when it is broken—not whilst it is flowing. In the case of the faradic current there is no difference between the poles, each being alternately an anode and a kathode many times a minute; in the galvanic current, on the other hand, the pole

connected to the zinc of the battery is known as the kathode, and it is by this that the current leaves the body, whilst the other pole is known as the anode, and by it the current enters the body. When testing muscles or nerves it is usual to have one pole in contact with an indifferent part, such as the spine, and the other over the motor point of the muscle or nerve to be tested. Broadly speaking, the best spot for stimulating a nerve is the place where it is most superficial, and for a muscle, over the site of entry of its motor nerve. It is important to have the skin well wetted, to minimize its resistance to electrical conduction; and the strengths of current required to produce contractions should be measured by a galvanometer, without which the relative excitabilities of the nerves and muscles of the two sides of the body cannot be compared.

Under normal conditions, both faradic and galvanic currents produce brisk contractions of a muscle when applied either to it or to its nerve; and with galvanism it is found that a weaker current will suffice to evoke a contraction on making the circuit when the kathode is on the muscle or nerve than when the anode is similarly employed. This is usually summarized by the formula K.C.C. - A.C.C., which means "the kathodal closure contraction is more easily obtained than is the anodal closure contraction". When the nerve is degenerated, however, there is a change in these electrical reactions, and when there is complete reaction of degeneration—often written and spoken of as R.D.—stimulation of the nerve itself evokes no muscular contractions whether the faradic or the galvanic current is employed, stimulation of the muscle evokes no contraction when the faradic current is used, whilst with galvanism the muscle can still be made to contract, though its method of response differs from the normal in the following respects:

1. It may be evoked by a strength of current less than the healthy minimum.
2. The twitch of the contraction is slow and sluggish, instead of brisk and quick.
3. It may be evoked at least as readily when the pole upon the muscle is the anode as when it is the kathode; the formulae A.C.C. - K.C.C., or A.C.C. - K.C.C., express this condition, the latter meaning that the anodal closure contraction is obtained from a smaller current than the minimum required for the kathodal closure contraction.

In this connection, however, two considerations require to be understood clearly. In the first place, if a given nerve were cut across with a knife, there would be no immediate R.D.; it takes a week or more for the process of nerve degeneration to reach the stage that produces R.D.; it then depends upon what happens to the nerve how long the R.D. persists: if regeneration occurs, it takes from twelve weeks onwards to complete itself, and R.D. will be found all that time; if the nerve does not regenerate, then R.D. may persist for two or three years or more, provided that the muscle fibres are kept, by massage and electrical treatment, from becoming mere strands of fibrous tissue. Should the latter change ensue, there will be no more electrical response in the fibrous tissue that used to be muscle than there would be in any other fibrous tissue.

In the second place, it happens, as often as not, that when some fibres in a nerve-trunk degenerate, others do not, and the same applies to the corresponding muscle fibres. It follows that there will then be a mixed reaction, the normal fibres giving a normal response, the degenerated fibres giving R.D.; the greater the proportion of degenerated fibres, the nearer will the reactions obtained approach to complete R.D., and vice versa. The result is spoken of as *partial R.D.*: some excitability both of the nerves and of the muscles to faradism remains, but it is less than normal; the nerve responds to galvanism, but not so readily as does the muscle when the latter is stimulated directly; the response of the muscle will be less brisk than normal, and yet K.C.C. may still be more easily obtained than A.C.C. It is by no means easy to be sure of the interpretation of a partial R.D., but partial is commoner than complete R.D.

The chief use of R.D. is in distinguishing muscular atrophy due to organic changes in the lower neuron from other cases of atrophy, especially when the latter is due to general wasting from cachexia, or to arthritis, or disuse, or a primary muscular dystrophy. When R.D. is present there is a lesion in the lower neuron, either in the anterior cornual cells, the anterior nerve-roots, or the peripheral motor nerve-fibres. The differential diagnosis of the various affections of these parts is discussed under *Atrophy, Muscular* (p. 78).

It remains to add that there are a few maladies in which the electrical reactions are peculiar, though they do not present R.D. In tetany, for instance, Erb has shown that A.C.C. is often greater than K.C.C., although in other respects the reactions are normal.

In Thomsen's disease there is variability in the polar responses, the original contraction produced on closure lasting a long while, and sometimes developing into a series of wave-like movements during the continuance of the passage of the constant current: but excitability to faradism remains. It is a rare malady, but one so characteristic that it is recognized easily: the chief feature of it is slowness of the relaxation of the muscles when they are first used after a period of rest. When the patient starts to rise from a chair, for example, he does so very slowly and as though he were stiff: the muscles are unduly rigid, and the first few steps he takes are consequently awkward and very slow: after a few seconds the peculiar delay in relaxation passes off and ordinary walking becomes possible. After sitting down again for a while, the same difficulty of rising and starting to walk ensues. There is no pain as a rule, which distinguishes the condition from true stiffness, ankylosis, or rheumatoid arthritis, which might otherwise be diagnosed in error. The legs are nearly always affected more than other parts, and the main complaint is that of difficulty in starting to walk or otherwise use the legs, this difficulty passing off after a few seconds or minutes.

In some cases of Raynaud's disease, and in angioneurotic edema and allied vasomotor neuroses, there may be variations from the normal reactions to galvanism. In myasthenia gravis (*Figs.* 245, 246, p. 291) it is characteristic that, whereas the affected muscles respond readily to the first few faradic stimuli, the contractions diminish rapidly in size and cease after a few minutes, notwithstanding the continuance of stimulation. After a period of rest this myasthenic reaction is obtainable again, and so on. This type of electrical response corresponds precisely to the rapid fatigue of the voluntary muscle movements, and the diagnosis is not difficult, though the disease is rare. *Herbert French.*

RECTUM, ABNORMALITIES FELT PER.

Method of Examination. The patient should be placed in a good light on a couch of convenient height. With male subjects the best position is the knee-elbow, with females the left lateral with the knees flexed and the left arm behind the back. The examination should be made with the right hand, leaving the left free for manipulations. Most diseases of the rectum are situated within two inches of the anus. It is advisable, therefore, that to begin with the finger should be inserted as far as the first joint only, and the lower inch of the bowel examined thoroughly. The examination must not be concluded until the finger has been passed up as high as possible and the whole of the rectum within reach explored, as well as the coccyx, sacrum, ischio-rectal fossae, and adjoining viscera. The rectal speculum and the sigmoidoscope may also be needed to complete the examination.

If any abnormality be felt the first thing to ascertain is: (1) *Whether it lies free in the lumen or is attached to the wall of the rectum*: (2) *Whether it is some abnormality of an adjoining structure or viscus that can be felt through the rectum.*

I. ABNORMALITIES LYING FREE IN THE LUMEN OR ATTACHED TO THE WALL OF THE RECTUM.

Foreign Bodies. Though faeces can hardly be considered as foreign to the rectum, yet a hard, scybalous mass, enterolith, or hair-ball may amount to an abnormality. True foreign bodies include those that have been introduced through the anus, and those that have been swallowed. Examples of the first class are seldom met with, and then are generally in persons of weak intellect. Thieves sometimes employ the rectum as a hiding-place for stolen goods—diamonds, for instance. The majority of foreign bodies felt per rectum have been swallowed—fishbones, pins, needles, splinters of wood. Their importance lies in the fact that they may cause a rectal or ischio-rectal abscess, and in treating such a case their discovery and removal is essential for a complete cure.

Swellings of the Rectum projecting into the Lumen.

Internal Hemorrhoids are rarely palpable to the finger unless chronically inflamed, thrombosed, or gangrenous. If palpable they will be felt immediately inside the anus, and can be hooked out with the finger and made to protrude through the anal orifice for inspection. The existence of piles having been diagnosed, an effort should be made to see if there is any causative condition, such as a carcinoma in the bowel above.

Abscess (submucous) gives rise to a more or less elongated, smooth, elastic swelling in the rectal wall. It is intensely tender, the slightest pressure causing great pain. The mucous membrane may feel hot, and pit on pressure. If the abscess has burst or bursts during examination, the finger on withdrawal will be covered with pus. An abscess that has already emptied itself feels like a small pea or bean in the submucous tissue.

Polypus is a term used to designate, without reference to its histological characteristics, any benign tumour that is pedunculated. Almost all innocent tumours in this position, even if sessile at the beginning, ultimately become pedunculated owing to the downward drag of the faeces. The passage of blood and mucus, combined with the absence of piles or carcinoma, should lead one to suspect the presence of a polypus. It may not be easy to feel, because its consistence is much the same as that of the mucous membrane, and because its peduncle may allow such free movement that it may easily be mistaken for a small mass of faeces. The best way of fixing these growths is to sweep the finger round and round the whole circumference of the rectum up to the highest point attainable. The growth is then arrested by the pedicle, and the finger can be hooked round it, so that the growth is drawn down and, if possible, made to protrude through the anus. If the polypus is large, a rectal speculum may be of service. Polypi are often multiple.

Ulcers, unless malignant or chronically inflamed, can rarely be felt with the finger: they must be viewed with the speculum or the sigmoidoscope. They may be tuberculous, gummatous, traumatic, or due to ulcerative colitis or dysentery.

Carcinoma occurs usually in people over forty. Its commonest site is within the four terminal inches of the bowel. It is generally hard, fixed, irregular, and nodular. Its extent varies with its stage: it may involve only part of the circumference of the bowel, or may extend right round so as to occlude the lumen and cause a stricture. The surface is usually ulcerating, so that it is friable and bleeds easily. There is nearly always a belt of normal mucosa between the internal sphincter and the neoplasm. Not only the lateral but the upper limit of the growth may sometimes be ascertained by inserting the finger to its extreme limit, care being taken not to split the mass. Another point to be gauged by a rectal examination is the degree of infiltration as measured by the fixity of the tumour to the neighbouring structures, e.g., sacrum and coccyx. Following the rectal examination, the abdomen is to be palpated for evidence of infection of the inguinal, pelvic, or lumbar glands, and the existence of secondary deposits in the liver.

The clinical symptoms of carcinoma of the rectum are suggestive. The patient generally complains of diarrhoea, the bowels being open five to twenty times a day, and this may have followed on a period of constipation. Notwithstanding the apparent diarrhoea the total amount of faeces passed is small, and no sense of satisfaction is obtained by the patient after stool. The evacuation may be so rapid as to merit the description 'explosive diarrhoea'. Haemorrhage from the bowel is common, and in the later stages there is a discharge of mucus. Pain is complained of a dull aching pain in the rectum and at the bottom of the back, which is not made much worse by the passage of a motion, quite unlike the sharp temporary excruciating pain associated with an anal fissure or ulcer. Emaciation is rapid, and a history of wasting and diarrhoea in a middle-aged patient should always lead to a careful examination of the rectum, and if nothing is to be felt with the finger, a sigmoidoscope should be used. A carcinoma is likely to be overlooked from carelessness and from not making an examination. Mistakes may, however, arise between carcinoma and an adenomatous polypus or ulceration, either traumatic, colitic, dysenteric, venereal, or tuberculous, around which much long-standing inflammation has caused thickening. The facts that a carcinoma is hard, the surface often excavated, and the edges nodular and everted, are generally sufficient. If real doubt exists, a piece of the ulcer may be removed for microscopic report.

Intussusception. Occasionally a piece of intussuscepted bowel may come down so far as to be felt per rectum. This condition is associated with the passage of blood and mucus, and therefore might be mistaken for a disease of the rectum proper. The fact that intussusception occurs nearly always in children, especially at the age of nine months or thereabouts, and causes intestinal obstruction, should make such a mistake easily avoidable. Chronic intussusception in an adult is uncommon; when it does occur it results as a rule from a pre-existing polypus or from a carcinoma.

Stricture due to carcinoma is dealt with above, but a few words remain to be said

about fibrous stricture. This may be present at the anal orifice, at the level of the upper border of the internal sphincter, or three to four inches up the rectum. It may be annular or tubular. The finger meets with a firm cord-like constriction, which perhaps will not allow the entrance of more than its tip; there will be no bleeding unless the finger is forced through the stenosis and the mucous membrane torn.

Fistulæ, either recto-vaginal or recto-vesical, whether congenital or acquired, may be felt with the finger. The passing of urine or feces by abnormal passages indicates the complaint.

Malformations of the Rectum. Some children are born without an anus, or without the lower portion of the rectum, or the finger introduced may be stopped by a membrane separating the upper from the lower portion of the bowel. The diagnosis is obvious. Two common types of the abnormality are shown in the accompanying diagrams, Figs. 575, 576.

Fig. 575.—Sagittal section of the pelvis of a male child, showing the rectum opening into the prostatic part of the urethra. A, Bladder; B, Rectum; C, Recto-vesical pouch; D, Uterus masculinus; E, Intra-urethral anus; F, Prostate; G, Proctodeum; H, External and internal sphincters; I, Cowper's gland.

Fig. 576.—Sagittal section of the pelvis of a female infant, showing the rectum opening into the navicular fossa of the vulva. A, Bladder; B, Rectum; C, Recto-uterine fold; D, Symphysis pubis; E, Vulva; F, Clitoris; G, Proctodeum (rarely present if the rectum opens into the vulva); H, Urethra; I, Clitoris; K, Hymen; L, Vagina.

II. ABNORMALITIES OF NEIGHBOURING STRUCTURES FELT PER RECTUM.

It does not lie within the scope of this article to give the differential diagnosis of all the morbid conditions that can be felt through the rectum: it suffices to take the structures within reach of the finger, and indicate the varying conditions in which a diagnosis may be aided by a rectal examination.

On the Anterior Wall the structures that can normally be felt are the prostate in the male, and the uterus in the female.

The Prostate.—Any enlargement is felt easily. An *adenoma* is the commonest form. This is soft, elastic, and has a groove in the middle line. A *carcinoma* or *sarcoma* is hard and fixed, and the outlines are blurred. A *prostatic abscess* causes a marked painful protrusion into the rectum.

The Vesiculæ Seminales are not palpable normally. The fact that they can be felt is almost sufficient to declare them diseased. They are affected most commonly in connection with tuberculosis of the testes or from present or past gonococcal vesiculitis.

The Bladder is not felt if healthy. If greatly distended it may form a tense resistance in the anterior wall of the rectum. Rarely, a large stone or a malignant growth of the floor may be felt.

The Uterus is easily palpable. Enlargement or retroversion or a pelvic fibroid can be recognized: the pressure of a foetal head may occlude the rectum.

The Vagina cannot be felt unless it is occupied by a foreign body such as a pessary, or is the seat of a growth.

The Ovaries, if enlarged by cystic disease or by new growth, may come within reach of the finger; *pyosalpinx* is often a bilateral affection in which the inflammatory masses can be felt per rectum in Douglas's pouch; they can be detected more readily by vaginal examination, however, when this route is permissible.

Through the Posterior Wall the only structures that can be recognized are the coccyx and sacrum.

The *Coccyx* may be found bent in and pressing on the rectum. In coccydynia any movement of the coccyx may cause great pain.

The *Sacrum* may be the seat of either a growth or an abscess, which will cause a bulging into the posterior wall.

On the two Lateral Surfaces no structures are normally recognized. The ischio-rectal fossa are common sites for *abscesses*, and these can be felt as tense swellings pushing in the wall. Rarely an *aneurysm* of the internal iliac artery or a *stone in the lowest portion of the ureter* may be felt. The *sciatic nerve* may be found to be very tender in cases of sciatica, or it may be felt definitely infiltrated by inflammatory, syphilitic, sarcomatous, or carcinomatous deposits: in rare cases a gumma of the sciatic nerve has been discovered on rectal examination, and this method of investigation should never be omitted in a in a case of sciatica.

If anything is felt with the tip of the finger through the upper portion of the rectum it will usually be something distending Douglas's pouch. This may be blood coming from a ruptured or leaking *ectopic gestation*, or a localized *abscess*, either parametric or arising from a septic Fallopian tube or the vermiform appendix. Some surgeons state that they are able to detect the appendix if it is hanging over the brim of the pelvis, but to do this the finger must be long and the senses very acute.

Sometimes, when there is doubt as to whether symptoms arising in connection with a more distant organ, e.g., the stomach or the gall-bladder, are due to malignant disease or not, rectal examination affords valuable evidence of malignancy even when there are no pelvic symptoms at all. When secondary deposits have arisen, they develop not infrequently in the pelvic peritoneum, presumably as the result of gravitation of malignant particles into Douglas's pouch. These latent secondary deposits can sometimes be felt very definitely as a firm band or shelf—the 'rectal shelf'—if the observer's index finger is a fairly long one. Rectal examination is sometimes of value also in verifying the existence of free fluid in the peritoneal cavity.

George E. Gask.

RECTUM, BLOOD PER. (See BLOOD PER ANUM, p. 96: and MELENA, p. 481.)

REDUPLICATION OF HEART SOUND. It seldom happens that the diagnosis in a particular case is influenced to any marked degree by the presence or absence of reduplication of either heart sound: nevertheless, the reduplication is sometimes so definite that it attracts special attention and needs interpretation. It has to be distinguished from triple sounds, particularly from the canter-rhythm that occurs with acute pericarditis and less often with dilatation of the heart from fatty change, especially in pernicious anaemia and other conditions of oligochromamia; and from the beginning of a mid-diastolic bruit at the impulse in a case of acute rheumatic endocarditis of the mitral valves. One can lay down no rules as to how these various sounds are to be distinguished: it can only be done by having heard them in other cases: sometimes, indeed, opinions differ as to whether the sounds heard in a given patient are due to a bruit or to a reduplication.

Reduplication of the first sound is rare, and to all intents and purposes it never occurs except at or near the impulse: it indicates some abnormality, but does not specify exactly what that abnormality may be. If there is no bruit the commonest cause is great hypertrophy of the left ventricle from granular kidney or arteriosclerosis, indicated by the big heart, high blood-pressure, urinary and retinal changes.

Reduplication of the second sound is common, especially in the pulmonary area (second left intercostal space close to the sternum). It generally indicates great relative increase in the intrapulmonary blood-pressure, so that the pulmonary valves close a fraction sooner than the aortic: the reduplication may alternate with simple accentuation (see p. 1), the commonest cause being mitral disease, especially mitral stenosis. Similar reduplication of the second sound may be heard at the impulse also in these cases, though more often the second sound here is weak or inaudible. The commonest cause for reduplication of the second sound at the impulse is great relative increase in the systemic blood-pressure—especially in cases of arteriosclerosis or granular kidney. The second sound in the aortic

area (second right intercostal space close to the sternum) is generally very loud and ringing, or even reduplicated at the same time. There are no other really important causes of reduplication of either of the heart sounds.

Herbert French.

REFLEX, PLANTAR.—(See BABINSKI'S SIGN, p. 87.)

REFLEX, PUPILLARY.—(See PUPIL ABNORMALITIES OF THE, p. 674.)

REGURGITATION OF FOOD THROUGH THE NOSE may be but a temporary accident, the result of an unsuccessful attempt to stave off a sneeze, a cough, or a burst of laughter when the mouth is full of food or fluid; or it may result from an explosive return of gas from the stomach or œsophagus, particularly after drinking gassy fluid such as soda-water, champagne, ginger-beer, cider, or beer. In such cases the diagnosis is generally obvious. Pathological regurgitation of food through the nose results from two main groups of causes, namely:—

1. Structural Imperfections of the Palate:—

Congenital: cleft palate

Acquired perforation: (i) traumatic,
(ii) syphilitic, (iii) malignant,
(iv) tuberculous, (v) actinomycotic.

2. Paresis or Paralysis of the Soft Palate or of the Pharynx:—

Post-diphtheritic
Post-operative
Syphilitic

The result of bulbar paralysis
The result of pseudo-bulbar paralysis
Cases of undetermined cause.

Simple inspection of the roof of the mouth is generally sufficient to decide whether the cause belongs to group 1 or to group 2. The median and symmetrical imperfection of a congenital cleft palate is obvious, and there is the history of the trouble dating from birth. There may be a harelip or other congenital abnormality at the same time. When an ulcerative process is still in progress there may for a time be some doubt as to whether it is syphilitic, malignant, tuberculous, or actinomycotic. The history may help, or the healing of the ulcer under the influence of mercury or iodide of potassium or salvarsan may indicate its syphilitic nature. If it is important to arrive at the correct diagnosis as early as possible, a small portion of the pathological tissue may be excised and examined microscopically, or Wassermann's serum test applied, or scrapings from the ulcer examined directly for the *Spirochæta pallida*, for tubercle bacilli, or for ray fungi. Tuberculous ulceration of the palate is rare, and is generally associated either with lupus or with definite phthisis. A new growth of the palate may be either epithelioma, endothelioma, or sarcoma, the distinction between these depending mainly on the microscope.

Diphtheria. If there is no structural defect of the palate, the regurgitation of food through the nose being due to paralysis, the most likely cause is previous diphtheria. The existence of the latter may have been recognized at the time, but the diphtherial attack may have been so slight as either to have caused no definite illness, or else to have been regarded as simple sore throat. The palate alone may be paralysed, giving rise to a nasal character of voice as well as to the regurgitation; or there may also be paresis of the ciliary eye muscles, causing difficulty in reading; or general peripheral neuritis affecting the limbs and heart. The trouble may not come on for three or four weeks after the diphtherial attack, and therefore it may no longer be possible to detect Klebs-Löffler bacilli in swabbings from the tonsils or fauces; but it is important to look for them, both directly and by means of cultures. Probably not a few cases ascribed to 'influenza', or to undetermined causes, are really post-diphtheritic. The paresis recovers in time, sometimes quickly, but often not until three months or more have elapsed.

Post-operative Cases.—The history in these cases will point to the diagnosis: the accident is rare, and as a rule the effects are temporary; it may happen during the removal of tonsils and adenoids.

Syphilitic Paralysis of the Palate is not common, and it hardly ever occurs by itself. It is a general rule that luetic affections of cranial nerves are multiple and often asymmetrical; thus there may be strabismus, or a laryngeal paresis, in addition to that of the palate; and there may be a history or other evidence of syphilis.

Bulbar Paralysis. When this affects the palate and causes regurgitation of food through the nose there have generally been other symptoms for some time. The malady is slowly progressive, and starts with paresis of the lips and tongue; swallowing is difficult, not so much because of the regurgitation as because the tongue is unable to thrust the bolus back between the fauces. The constant dribbling of saliva from the angles of the mouth is characteristic of some cases. The title labio-glosso-pharyngo-laryngeal paralysis indicates the usual sequence of events. Bulbar paralysis may be associated with progressive muscular atrophy (p. 80), and it may be distinguished from pseudo-bulbar paralysis by the atrophy of the tongue, which occurs in the former but not in the latter. Bulbar paralysis is due to a lesion in the medulla oblongata, whereas pseudo-bulbar paralysis, with similar symptoms but no wasting of the tongue, is due to bilateral cortical softening. In either case the patients are generally elderly.

Undetermined Causes. As regards such cases, it may be repeated that the majority are doubtless post-diphtheritic, so that it is important to examine swabbings from the throat of all such patients for the Klebs-Löffler bacillus. The symptom is rarely hysterical.

Herbert French.

RETENTION OF URINE. (See MICTURITION, ABNORMALITIES OF, p. 490.)

RETRACTION OF THE ABDOMEN. (See RIGIDITY OF THE ABDOMEN, p. 734.)

RETRACTION OF THE GUMS is occasionally a symptom which troubles patients very much, but in itself it seldom indicates more than a local affection. In a mild degree it may be due to excessive use of a hard toothbrush; in most cases it results from a local infective process, especially tartar, caries of the teeth, or pyorrhea alveolaris. These conditions are discussed under the heading of BLEEDING GUMS (p. 93), though retraction may be present, even in an extreme degree, without actual bleeding.

Herbert French.

RETRACTION OF THE HEAD may be a marked symptom in the following conditions:

Acute meningitis:	Superior longitudinal sinus	Strychnine poisoning
Suppurative	thrombosis	Tetanus
Tuberculous (basal)	Acute encephalitis	Hydrophobia
Meningococcal (posterior	Bronchopneumonia with	Catalepsy
basal)	partial asphyxia	Spasmodic torticollis
Meningococcal (epidemic	Laryngeal obstruction, espe-	Paramyoclonus multiplex
cerebrospinal)	cially diphtheria in chil-	Hysteria and hystero-
Cerebellar or other subten-	dren	epilepsy.
torial tumour or abscess		

In arriving at a diagnosis in any given case the probability is that *strychnine poisoning*, *tetanus*, and *hydrophobia* will either suggest themselves at once on account of other circumstances in the case, or else will not need to be discussed at all. *Hysteria* can only be diagnosed when all other possibilities have been excluded, and probably not until the case has been watched anxiously for a time; there may be other functional symptoms in the case (p. 570); the patient is generally a young adult, more often female than male. *Catalepsy* and *hystero-epilepsy* will be suggested by the mental symptoms of obvious insanity.

These things being excluded, the first thought that marked and maintained retraction of the head arouses is that the patient has some serious intracranial lesion, probably *meningitis*. Before coming to this conclusion, however, it is important not to forget that extreme dyspnoea in children sometimes produces considerable head retraction, so that the physical signs in the lungs and heart should be noted carefully, *bronchopneumonia* and *capillary bronchitis* being kept specially in mind, and any signs of *laryngeal obstruction* looked for, especially stridor and spasmodic up-and-down movements of the thyroid cartilage, with sucking in of the thorax above and below the clavicles, along the attachments of the diaphragm, and in the intercostal spaces. *Diphtheria*, *foreign body in the larynx*, and *retropharyngeal abscess* have all been mistaken for meningitis.

If there is no evidence of sufficient throat or lung trouble to account for the symptom, an intracranial lesion is probable; and by far the most likely, especially in a child, is acute

meningitis, either tuberculous or posterior basal. Symptoms common to all the intracranial affections are headache, vomiting, and giddiness; pyrexia, generalized convulsions, coma, incontinence of urine and faeces, retraction of the head, and optic neuritis; or local symptoms, especially twitchings, convulsions, or paralysis of individual limbs or parts of limbs, according as one part of the brain or another is more irritated or softened than the rest. If there is an obvious source of sepsis in connection with the cranium, such as otitis media, mastoid abscess, facial erysipelas, a septic scalp wound, boils, pediculi with sores, suppuration in the orbit, nose, antrum of Highmore, frontal ethmoidal, or sphenoidal air-cells, or nasopharynx, the probability is that any acute meningitic symptoms are due to staphylococcal or streptococcal *suppurative meningitis*; *pneumococcal meningitis* may occur without local sepsis, either alone or as part of a general pneumococcal septicaemia; suppurative meningitis due to the *Bacillus diphtheriae*, the typhoid bacillus, influenza bacillus, or the *Bacillus coli communis* may occur, but it is decidedly uncommon and clinically indistinguishable without bacteriological cultures of the cerebrospinal fluid from other forms of suppurative meningitis, in all of which marked pyrexia and a fatal ending in two or three days are the rule. *Tuberculous meningitis* is much commoner in childhood than it is at any other age; it is always part of a general

Fig. 577.—Photograph showing a positive Kernig's sign in a case of meningococcal meningitis. The leg cannot be extended on the thigh when the latter is at right angles to the trunk. Note the tension on the tendons of the hamstring muscles. (Kindly lent by Major Chapman.)

tuberculosis, and it is rare in adult life. At first there may be no pyrexia, though this depends on the caseous glands and tuberculous lesions in the lungs and elsewhere more than upon the meningitis. The early diagnosis is apt to be uncertain, but as the days go by the serious nature of the complaint generally becomes obvious: the effortless vomiting, the irregular pyrexia, severe headache, optic neuritis, retracted head, possibly choroidal tubercles (Fig. 429, p. 520) or evidence of tuberculous foci elsewhere, serve to clinch the diagnosis. The chief difficulty, after the stage of retraction has been reached, is to decide between tuberculous meningitis on the one hand and *meningococcal (posterior basal) meningitis* on the other. The duration of the disease is often of assistance in this respect—suppurative meningitis kills in two or three days, tuberculous meningitis in two or three weeks, whilst posterior basal meningitis ends in recovery in a variable percentage of cases, even after continuing for two or three months. The

tendency to head retraction is greatest with the posterior basal, least with the suppurative forms. Kernig's sign (Fig. 577) is generally present in all forms of meningitis. Optic neuritis barely has time to develop in suppurative meningitis, but it is present more often than not in both basal and posterior basal meningitis. The way in which the heels touch the occiput in some cases of the latter may by itself decide the diagnosis. Another point in favour of meningococcal meningitis is the occurrence of periodic spike-like rises of the temperature chart—pyrexial 'crises' lasting twenty-four hours or less (Fig. 578), and superposed upon what is otherwise a chart of but moderate type. When doubt remains as to the fact of meningitis or as to its nature, microscopical and bacteriological examinations of the cerebrospinal fluid obtained by lumbar puncture will often serve to establish the diagnosis (p. 382). Bacteriologically, tubercle bacilli are the least easy to find. The Gram-negative meningococci (*Diplococci intracellulares meningitidis Weichselbaumii*) are characterized by their occurrence within the leucocytes in pairs, like gonococci, but without the reniform shape of the latter. The organisms of suppurative meningitis may be discovered on direct staining, but more often cultural methods are required.

Where posterior basal meningitis ends and *epidemic cerebrospinal meningitis* begins, it is difficult to say: they are both meningococcal, and probably they are only different types of the same malady, connected together by sporadic cases in which posterior basal meningitis is associated with more or less severe spinal symptoms. The way in which

the least touch or movement causes the patient to cry out with pain sometimes indicates how inflamed the coverings of the posterior nerve-roots are, besides which, the erythematous, vesicular, or purpuric skin eruptions that may accompany it often suggest the diagnosis. There is less difficulty during an epidemic: it is the sporadic case that may be missed. The clinching point in the diagnosis is bacteriological investigation after lumbar puncture, assisted perhaps by the beneficial effects of the specific antimeningococcal serum.

Superior longitudinal sinus thrombosis and *acute polio-encephalitis* are both apt to be diagnosed as acute meningitis in the first instance. It is when a case that has simulated acute and severe meningitis, with coma and apparently impending death, gets rapidly better after a few days and ends in speedy recovery, with or without some

Fig. 578. Four-hourly temperature chart in a case of meningococcal cerebrospinal meningitis. The pyrexial crises are even more marked in some cases. The diagnosis was verified at autopsy.

impairment of local or general brain functions, in a child or young person, that one changes one's diagnosis of meningitis to polio-encephalitis. If acute cerebral symptoms in a previously healthy child end in a gradual but partial recovery, accompanied by permanent spastic paralysis of the legs, without much affection of the arms, it is very possible that the lesion has been thrombosis of the superior longitudinal sinus, with softening of the leg areas of cortex on either side of it.

Cerebellar or other *subtentorial tumours* or *abscesses* generally cause a much more gradual onset of symptoms than do any of the above. Head retraction is not present until the later stages. The diagnosis of tumour will rest on the slow increase in the signs of raised intracranial pressure, with nystagmus, optic neuritis going on to optic atrophy, and a tendency to fall always in one definite direction forwards or backwards if the tumour is in the vermis, to the right or to the left according as it is in the right or left hemisphere. There is often marked ataxy, with exaggeration of the tendon reflexes, particularly on the same side as the tumour. If nystagmus is well marked this serves as a point of some value in distinguishing a cerebellar from a cerebral tumour. Abscess is distinguished from tumour chiefly by the existence of some obvious cause for intracranial

abscess, otitis media, for instance, or bronchiectasis. Cerebellar abscess may give rise to no pyrexia and no leucocytosis; but whether the temperature is raised or not, the pulse-rate is often absolutely slowed.

It is noteworthy that one meets every now and then with a case in which all the symptoms, including head retraction, seem to point to acute meningitis of a fatal type, and yet spontaneous recovery takes place without any definite diagnosis seeming to be possible even after lumbar puncture and examination of the cerebrospinal fluid. Some of these cases may be examples of abortive meningococcal meningitis; others seem to be serous meningitis secondary to otitis media non-fatal meningitis due to suppurative organisms which stop short of producing pus; and so on. To such cases of inconclusive acute meningitis the term *meningismus* has sometimes been applied; apparently meningismus means "I thought at first there was meningitis, but as the patient has recovered I suppose I was wrong."

Herbert French.

RIGIDITY OF THE ABDOMEN is a sign not to be regarded lightly, and one to find the true significance of which may call for great skill. The patient should be examined lying on the back with the whole of the abdomen and lower thorax exposed. The observer, seated on a level with the patient, should watch the abdomen for a minute or so and see whether it moves or not with respiration, and whether one part moves more than another.

Some nervous patients, especially if the room is cold, hold their abdomens intensely rigid in a wholly unnecessary way, a tendency which may create a false impression. This can be avoided by engaging them in conversation for a minute or two, by asking them to take a few deep breaths, or by making them draw their knees up and keep their mouths open, when the normal abdominal walls will generally relax.

There are varying degrees of rigidity. The whole abdomen may be rigid, the upper or lower part only, or one side, as in the presence of a localized appendicular abscess. Again, one part or one rectus muscle may be put, as it is termed, 'on guard' whenever the patient thinks a tender spot is about to be touched. The rigidity over an inflamed gall-bladder, and that over a gastric or duodenal ulcer, are instances of this.

The most important cause of universal rigidity is *Septic Infection of the Peritoneum*, which may follow external wounds, abdominal operations, childbirth, abortion, endometritis, parametritis, extension of inflammation from or perforation of the appendix, ulcer of the stomach, duodenum, or bowels, perforation of the gall-bladder, suppurating Fallopian tube, or abscess of the liver, spleen, or kidney; or which may be primary, as in some pneumococcal cases. It is a safe rule to believe there is peritonitis until the contrary is proved. As in the case of other disease diagnosis must not be based on one clinical sign, and the patient must be examined for the other signs of peritonitis.

The history of the onset is important. In perforative cases, the beginning is marked by intense abdominal pain. This may be general and continuous, or by being referred to the stomach or appendix region give an indication of the primary seat of the mischief. The position taken up is on the back, sometimes with the knees drawn up to relieve abdominal tension, and the patient generally lies still, for any movement causes increase of pain. In colic, on the contrary, whether intestinal, biliary, or renal, the patient rolls about during the spasms. It is painful to use the diaphragm; therefore, respiration is superficial and costal in type. The abdomen gradually becomes distended, tense, and tympanitic; the liver dullness which was previously present may disappear, and in some forms of peritonitis fluid may accumulate in the abdomen and be detected by the signs of shifting dullness in the flanks. The pulse is small and rapid, 100 to 150, and tends to quicken when it is recorded at intervals. A friction rub may be heard over the liver or the spleen when the patient breathes. Borborygmi will generally be absent. Vomiting is an early, prominent, and almost constant feature. The contents of the stomach are ejected first, then bile-stained fluid, and later green or brownish fluid with a slight faecal odour. The vomiting is often of a peculiar 'pumping' character. The bowels may be loose at first and then constipation follows, but is not complete as in intestinal obstruction. Micturition may be frequent, or there may be retention when the pelvic peritoneum is acutely inflamed. When the disease is well developed the appearance of the patient is characteristic, exhibiting the 'Hippocratic facies'. The pulse is often of great assistance in arriving at a diagnosis

of the need to operate urgently in these cases: it should be counted every ten minutes: if its rate falls or does not rise at successive counts peritonitis is less probably present than when the pulse-rate is found to be rising each time.

In suppurative peritonitis leucocytosis, though it may not occur at all, is often marked (15,000 to 30,000 per c.mm.).

It does not necessarily follow, because the whole abdomen is rigid, that the peritonitis is general. For instance, in cases of perforative appendicitis it has been shown by operation that pus was only to be found around the caecum, and yet there was general rigidity. Without operating it is often impossible to tell. The best way of finding out whether there is pus in the abdomen, and the method to be employed at once if there is any doubt, is to open the abdomen and see.

OTHER CONDITIONS ASSOCIATED WITH ABDOMINAL RIGIDITY WHICH MAY BE MISTAKEN FOR PERITONITIS.

Pneumonia or Diaphragmatic Pleurisy. In the early stages here, before the onset of dullness in the lungs and other physical signs in the chest, the most prominent features may be abdominal pain and rigidity. Laparotomy has often been performed on the mistaken diagnosis of peritonitis. If, however, the examination is thorough, signs pointing to implication of the lungs will usually be found. Rapidity of respiration, working of the nares, and blueness of the lips should receive particular attention. An examination of the blood may reveal a high leucocytosis (30,000 to 40,000): in suppurative peritonitis the numbers are rarely so high.

Colic. The suddenness of the onset of pain, its intense character, and the abdominal rigidity, may render this condition extremely difficult to differentiate from peritonitis due to perforation of some viscus. Collapse may be marked, and the effect on the pulse is considerable: vomiting is common also. The temperature is raised slightly but rarely exceeds 100° F., and the pulse, though it may be rapid, does not tend to quicken progressively. The pain is spasmodic, not continuous as in peritonitis, and is generally relieved in a few hours. Biliary and renal colic are fairly characteristic, but that due to lead, the crises of tabes dorsalis, or gastro-intestinal disturbances may easily be mistaken. The gums are to be examined for a blue line, the knee-jerks and pupils tested, and a blood-count made. In uncomplicated colic there is no leucocytosis. In cases of extreme difficulty the abdomen may have to be opened. The persistence of borborygmi is in favour of colic rather than of general peritonitis.

Intestinal Obstruction. The vomiting and constipation here present may lead one to think of peritonitis, and indeed the two conditions may be present at the same time, as in the case of an ulcerating carcinoma of the bowel. Usually the rigidity is not well marked, and the constipation, which is not absolute in peritonitis, is here complete.

Injuries of the Abdomen.

1. Contusion of the abdominal wall, with laceration of muscle: Particularly in patients who have been run over across the abdomen, rigidity is a marked feature, and there must always be a doubt at first as to whether any of the viscera have been torn and are bleeding, or whether the escape of their contents is setting up peritonitis. In the case of mere contusion, if the patient is put to bed and kept warm, collapse will soon disappear, the abdomen will become less rigid, and the pulse-rate will fall.

2. Contusion of the abdominal wall with injury of viscera: The signs here will be more marked, and instead of tending to diminish rapidly will become worse. If there is internal bleeding the mucous surfaces will be pale, the skin cold and clammy, and the pulse small and frequent. If the contents of a viscus have escaped, the signs of peritonitis will develop rapidly. In all cases of doubt an exploratory laparotomy should not be delayed.

Ruptured Tubal Gestation. This may simulate general peritonitis. The abdominal rigidity here is not well marked, and the signs of bleeding are. A moderate degree of leucocytosis is present (10,000 to 15,000), but the number of red cells is diminished. If the patient is a woman of the child-bearing age, known to be a week or more overdue as to monthly period, and has begun to lose blood per vaginam synchronously with the onset of acute abdominal pain and pallor, the diagnosis will suggest itself at once.

Acute Hemorrhagic Pancreatitis is usually diagnosed as intestinal obstruction or acute perforative peritonitis. The attack sets in with intense pain, usually in the upper and left part of the abdomen. Vomiting, constipation, and tympanitic distention are present. The condition is so rare, and the signs are so unreliable, that an exploratory laparotomy should be made, and the nature of the case becomes obvious directly the characteristic opaque yellow patches of fat-necrosis (see *Fig. 625*, p. 810) are seen in the omentum.

Rupture of an Abdominal Aneurysm, Dissecting Aortic Aneurysm, Embolism of the Superior Mesenteric Artery, may simulate peritonitis, and so also may *Acute Thrombosis of the Inferior Vena Cava*; but all these conditions are rare, and they will be very difficult of diagnosis unless the existence of some cause for them, such as aortic aneurysm or fungating endocarditis, is already known. *Local Necrosis of a Compartment of one Rectus Abdominis Muscle*, especially in the lower half of the latter, leads to acute local pain, tenderness, or rigidity which may simulate appendicitis, for example, so closely that operation is undertaken: the muscle fibres of the abdominal wall will be found in a deep red pulpy hemorrhagic state, the cause apparently being acute thrombosis of the nutritive vessels in the course of an infective illness: the condition is not altogether rare in acute epidemic influenza, and it is also met with in typhoid fever.

Acute Suppurative Nephritis sometimes gives abdominal rigidity, and is associated with fever and vomiting. There is always marked tenderness in the loin on the affected side, and the urine will contain albumin, pus, blood, casts, and bacteria. The milder types of the infection (see BACTERIURIA, p. 88) may be mistaken for acute appendicitis, or for general peritonitis, unless the centrifugalized deposit from the urine is examined microscopically for pus.

George E. Gask.

RIGORS, or CHILLS, are common at the onset of the most various acute febrile disorders, and may occur at regular or irregular intervals in the course of many of the more severe of them. The chief sign of a rigor is shivering, the chief symptom a feeling of cold and general wretchedness. At its beginning, the patient looks chilly, pinched, and blue, and sits or lies huddled up, complaining of the cold: his arteries are contracted, the pulse is rapid, small, and of raised tension: the extremities are chilled superficially, but the internal temperature is above the normal. Very soon the sensation of cold induces involuntary shivering: the patient shakes all over, sometimes so violently that the chair or bed vibrates: the teeth chatter, and even the muscles of the face twitch involuntarily. This shivering lasts for minutes, or even for an hour, dying away gradually as the patient feels himself to be warmed up. Thus the initial stage of the fever passes into the second stage or fastigium, in which the complaint is of sweating, thirst, and undue heat, and the body temperature rises still further. In children, general convulsions, with partial or complete coma, may occur at the onset of an acute infection, in conditions that would give rise to a rigor in adults. In adults, convulsions are not known to take the place of rigors. Cases may arise, however, particularly when only an imperfect history can be obtained, in which it may be hard to say whether a patient has had a rigor, or an epileptiform, hysterical, or epileptic fit. Should the patient have lost consciousness during the shivering, or have fallen down, bitten his tongue, or passed his water during the attack, or should he give a history of similar attacks on previous occasions, the diagnosis of epilepsy would be more than probable. Epileptiform fits that unskilled observers might confuse with rigors may occur in uræmic or eclamptic patients: the history of the case, and the discovery of albumin in the patient's water, together with other evidences of acute or chronic renal disease, should make the diagnosis clear. Fits indistinguishable from rigors to the untrained eye may occur in hysteria: in these, however, the shivering patient would be red in the face, or at least would not present the slightly livid and shrunken facial appearance characteristic of a rigor, the temperature would not be raised, and the signs or a history of other hysterical phenomena should be obtainable.

For their further consideration it is convenient to classify rigors according as they are single or multiple.

1. **Single Rigors.**—The occurrence of a *single rigor* at the outset of an acute infectious disorder is extremely common when the infection is severe: in lobar pneumonia this initial rigor is often particularly long and severe. No exhaustive list of the disorders that may

be thus ushered in can be given; but it may be stated generally that an initial rigor is common in :-

Lobar pneumonia	Relapsing fever	Trench fever
Small-pox	Erysipelas	After injections of :-
Influenza	Cerebrospinal fever	Salvarsan and its allies
Severe feverish colds	Acute poliomyelitis	Colloidal manganese and its allies
Septicæmia	Malaria	Peptone
Pyæmia	Yellow fever	Serum
Pneumonic tuberculosis	Weil's disease	Some vaccines
Typhus	After catheterization	After blood-transfusion.

It is less often seen in :

Scarlet fever	Tetanus	Acute gastro-intestinal disorders
Measles	Miliary tuberculosis	Nephritis
Diphtheria	Sapremia	Cholelithiasis
Tonsillitis	Glanders	Renal calculus.
Rheumatic fever	Sick headache	

And is comparatively rare in :

Enteric fever	Anthrax	Dysentery
German measles	Hydrophobia	Malta fever
Mumps	Cholera	Beri-beri
Gout	Plague	Secondary syphilis.

The diagnosis of all these different morbid conditions must naturally be made from the history of exposure to infection, of some therapeutic injection, or from the subsequent signs and symptoms. It is clear that the occurrence or non-occurrence of an initial rigor will rarely be of much practical assistance in determining the nature of the disorder from which any given patient is suffering.

A rigor after catheterization is not rare, whether the kidneys be sound or no, and in some cases is due to septic infection of the urethra or bladder. In others, however, it ensues when no infection has taken place, and is not followed by any evidences of urinary sepsis; in these instances the rigor must be referred vaguely to nervous shock, and need not give rise to alarm.

2. **A Second Rigor** coming on in the course of any of these disorders, or a rigor occurring unexpectedly for the first time when the disease is well established or declining, is often evidence of the spread of the infection, or of the occurrence of some complication. For example, a second rigor occurring in the course of *lobar pneumonia* may coincide with the appearance of signs indicating the spread of the disease to the second and previously sound lung; a second rigor happening after the crisis may indicate an empyema. In *enteric fever* a rigor is rare, though it may be due to such complications as perforation of the intestine, acute peritonitis, pleurisy, pneumonia, middle-ear disease, periostitis; but there is an abnormal type of enteric fever in which rigors occur for no apparent reason, followed by heavy sweats; and rigors may be observed in cases with constipation, or during defervescence, or in enteric patients who have been treated with antipyretic drugs.

3. **Recurring Rigors.** The occurrence of a *series of rigors* often gives information of more definite value, for they are seen in but a limited number of local or general infections, most of which have some characteristic or localizing signs. In themselves these rigors are no more than evidence of the severity of the infection, and of the extent to which bacterial toxins have been absorbed into the blood. The following are the chief disorders characterized by a series of rigors :-

Malaria tertian, quartan, astivo-autumnal or malignant	Acute blood-infections, including :-	Special forms of these may be known as puerperal fever, malignant endocarditis, acute infective osteomyelitis, suppurative pyelophlebitis, etc.
Relapsing fever	Portal pyæmia	
Acute leucæmia	Pyæmia	
Trench fever	Septico-pyæmia	
	Septicæmia	
Acute inflammations, e.g. :-	Abscess formation :-	Pulmonary tuberculosis
Pyelitis	Hepatic (tropical)	Bronchiectasis
Pyelonephritis	Appendicular	Enteric fever
Cystitis	Subphrenic	Erysipelas
Cholecystitis	Perinephric	Rat-bite fever
Empyema	Prostatic	Influenza.
Infective sinus thrombosis	Cerebral	

A very thorough physical examination of any patient presenting multiple rigors should be made : the condition is always serious, and may be due to septic absorption from some deep-seated abscess that produces only the scantiest of physical signs. When no abnormal physical signs can be found bacterial cultures should be made from the circulating blood, care being taken to draw off a sufficient quantity of blood 5 to 10 c.c. and to repeat the cultivation several times before it is decided that the blood-stream is sterile. Blood cultures are more likely to be successful if the patient's temperature is 102° F. or over at the time the blood sample is taken than if they are made when the patient's temperature has fallen below this level.

In *malaria* the rigors tend to recur at regular intervals of forty-eight (*Fig. 51*, p. 37) or seventy-two hours (*Fig. 52*, p. 38) in the benign tertian and quartan infections, at shorter intervals if the infection is mixed. In the astivo-autumnal form the rigors and also the course of the fever are much less regular (*Fig. 55*, p. 39). The parasite (*Figs. 57-60*, pp. 40, 41) may be found in the circulating blood, and the patient, if not *in extremis*, is cured by quinine : there is no leucocytosis, but a relative increase in large lymphocytes occurs.

In *relapsing fever* the onset is acute, with a rigor or a series of rigors. A fortnight later, when the patient has been convalescing for a week or ten days, relapse and a second rigor or series of rigors occurs (*Fig. 48*, p. 36). A second relapse may be noted at the end of the third week, and in a very few cases a third relapse. Relapsing fever has practically died out of the United Kingdom, but it is met with in Egypt, India, and other countries. It occurs in epidemics, especially during periods of distress, famine, and privation when infection spread by bug-bites is specially prone to occur, and Obermeier's spirochæte (*Fig. 606*, p. 779) can be found in the patient's blood while he is feverish.

Multiple rigors occur exceptionally in the course of *acute blood-diseases*, such as acute leukæmia, pernicious anæmia, or Hodgkin's disease. Severe and progressive anæmia, wasting, fever, heavy sweats, and hæmorrhage from the mucous membranes, are likely to occur in these cases, with characteristic changes in the microscopical appearances presented by the blood (p. 30).

Multiple rigors are commonest in the various forms of *acute blood-infections* : special forms of these have received particular names. Thus *puerperal fever* occurs after delivery, and is due to bacterial infection of the uterus and its spread thence to the blood ; the patient will probably have a sanious or offensive vaginal discharge as well as the evidences of septicæmia or pyæmia. In *malignant endocarditis*, attention is directed mainly to the condition of the heart, the presence of valvular murmurs, and the signs given on p. 45. In *acute infective osteomyelitis* the first complaint arises from the acute inflammation occurring in the marrow of one of the bones. *Portal pyæmia* or suppurative pylephlebitis is seen in patients with various acute inflammatory intra-abdominal lesions, and is due to the spread of bacterial infection to the liver through the portal vein. The commonest precursor is mild appendicitis. The blood in the portal vein clots, the clot is infected with microbes, softens, and breaks up, to be dispersed throughout the liver in the form of infective emboli. Multiple hepatic abscesses result, with pain, swelling, and tenderness in the hepatic region : jaundice is present in less than half the cases, with more or less coloured stools, vomiting and diarrhœa are frequent, and there is hectic fever. *Pyæmia* is characterized by the formation of metastatic abscesses in any of the tissues or organs, oftenest in the subcutaneous tissues or in the lungs in consequence of the lodgement there of multiple infected emboli. Before the days of antiseptic or aseptic surgery pyæmia was the common outcome of serious surgical operations or severe wounds : nowadays it is comparatively infrequent, and when it does occur is secondary to a severe infected wound, to ulcerations of the mucous surfaces, or to deeply-seated abscesses that are not amenable to surgical treatment. Occasionally it seems to be idiopathic, or due to some infective lesion that escapes discovery. Pyæmia oftenest begins suddenly ; the main symptoms are hectic fever, rigors, leucocytosis, diarrhœa and vomiting, heavy sweats, prostration, and the formation of secondary abscesses due to the arrest of septic emboli. When the lungs become the seat of multiple abscesses the breathing becomes rapid, and signs of bronchitis, pleurisy, or pulmonary consolidation appear. Abscesses in the more superficial tissues or joints make their presence known by the local evidences of pain, swelling, redness, and heat ; in the deeper parts of organs, by pain and disturbance of function. The development of secondary subcutaneous abscesses is common in the less

acute cases; abscess-formation in the heart, and suppurative pericarditis, are prone to occur when the primary lesion is a periostitis or an acute necrosis of bone. Pyæmia may be distinguished from enteric fever only with great difficulty if evidences of abscess-formation or some source of primary infection are not forthcoming, especially as the typhoid state is common in the later stages of both diseases; the occurrence of multiple rigors is rare in enteric fever, common in pyæmia; Widal's reaction should be tested for; and whereas in pyæmia there is generally leucocytosis and a rise in the polymorphonuclear count, in enteric fever there is leucopenia and a rise in the lymphocytic count. From malaria, pyæmia is distinguished by not reacting to quinine; malarial parasites will not be found in the circulating blood; in malaria there is leucopenia with a rise in the count of large hyaline corpuscles in the blood. Pain and inflammation in the joints after childbirth or a miscarriage may be diagnosed as rheumatism when the condition is really one of pyæmia or puerperal fever.

The precise diagnosis between pyæmia and septicæmia is often impossible, and is indeed of academic rather than clinical interest. The necessity for it is in part avoided by the use of the term *septic-pyæmia*, the evidences of which are much the same as those of pyæmia: all three conditions may arise from identical causes, and bacteria (streptococci, staphylococci, gonococci, pneumococci, *B. coli communis*, *B. typhosus*, *B. influenzae*, *B. pyocyaneus*, etc.) may be cultivated from the circulating blood in any of them. Multiple rigors are far commoner in pyæmia where several may occur daily than they are in *septicæmia*. The latter condition is due to the growth of microbes in the blood without the formation of metastatic abscesses: it originates in lesions very similar to those that underlie pyæmia, or results from infected but apparently trifling cuts or injuries, or even from neglected chronic suppuration about the teeth or in the tonsils. Its main symptoms are pyrexia, debility, anæmia; in severe cases rigors occur, and the patient may fall into the typhoid state. The bacteria causing it can be cultivated from the circulating blood; septic rashes or purpura are often seen in both pyæmia and septicæmia, but they are not seen in enteric fever. It should be noted that, at the best, a deal of looseness attaches to the meaning of the term septicæmia: for in lobar pneumonia, enteric fever, Malta fever, and many other acute febrile disorders, the specific microbes can habitually be cultivated from the circulating blood; technically speaking, therefore, these are all instances of septicæmia, yet they are not generally regarded clinically as septicæmias in the ordinary sense: to overcome this difficulty two new terms have been devised for conditions of this sort, namely, *bacillæmia* and *bacteriæmia*.

Multiple rigors may result from *acute localized inflammatory infections*, if the inflammation is sufficiently extensive and the infecting micro-organism virulent. It is often impossible to say how far such rigors are evidence of the absorption of toxins, and how far they indicate that living bacteria have gained access to the blood-stream. If situated in the genito-urinary tract, these inflammations are often associated with a history of *gonorrhœa*, *renal calculus*, or *gout*, and produce characteristic pathological changes (hæmaturia, pyuria, albuminuria) in the urine, or difficulties in micturition. If the gall-bladder or bile-ducts are the seat of the inflammation, jaundice and pain in the hepatic region will probably be observed with the fever and rigors, and a history of gall-stone colic may be given, *suppurative cholecystitis* or *suppurative cholangitis* having supervened; the gall-bladder will be tender and probably enlarged from the former, the whole liver swollen and possibly tender from the latter; Charcot's hepatic intermittent fever is due to *chronic cholangitis*, with intermittent biliary obstruction due to a ball-valve stone often lying in the ampulla of Vater. The occurrence of rigors in a child convalescing from pneumonia, measles, scarlet fever, or pleurisy, may lead to the discovery of an unsuspected *empyema*. *Infective sinus thrombosis* occurs mainly in patients with otorrhœa, and indicates that the bacterial infection has spread from the ear to one of the cranial venous sinuses. Its symptoms are general those of septicæmia or pyæmia, often with an initial rigor and vomiting followed by high fever, more rigors (*Fig. 553*, p. 694), and sweating; and local—very severe pain about the ear, excruciating headache, and venous congestion of the optic disc, with others that vary with the site of the thrombosis. If the sigmoid sinus is thrombosed, œdema and tenderness over the mastoid appear, and should the clotting spread downwards a thrombus may be felt in the internal jugular vein. Thrombosis of the cavernous sinus is accompanied by squint, exophthalmos, and œdema of the orbits

and eyelids. Thrombosis of the superior longitudinal sinus may set up oedema of the scalp near the sagittal suture. The diagnosis must be made from cerebral or cerebellar abscess, in which repeated vomiting is likely to occur, and the localizing signs and symptoms will suggest brain-disease; and from meningitis, in which rigors are rare. In other patients, some acute inflammatory disorder may result in definite *abscess formation*, when rigors may develop from toxic or septic absorption; here again, the virulence of the particular microbe causing the inflammation will be the chief factor in determining whether rigors occur or not. In many cases the rigors will really be due to a secondary and probably terminal septicæmia or pyæmia.

Tropical abscess of the liver, usually single, occurs in patients who have been abroad and have had dysentery, whether amœbic or bacterial. The early symptoms of liver abscess are often obscure, malaise, fever, sweating, rigors, and gastro-intestinal disturbances occurring, or a pleural effusion secondary to spread of infection through the diaphragm, while nothing particularly suggests implication of the liver. As a rule, complaint of dull pain in the right hypochondrium, axilla, or shoulder will be made.

Multiple rigors may occur from septic absorption in various diseases of the lungs, the most important of which are *bronchiectasis*, and advanced *pulmonary tuberculosis* with secondary pyogenic infection of the bronchi or tuberculous cavities. In either case the sputum will be abundant; it is often offensive in bronchiectasis and in tuberculosis it may contain elastic fibres.

High or irregular fever with recurring rigors has been recorded in a few unusual cases of *enteric fever* and of *influenza* free from any complication, and in *erysipelas* (Fig. 556, p. 699).

Rat-bite fever is probably commoner than might be supposed: it is apt to escape recognition. It occurs in persons who have been bitten by rats, or by ferrets, cats, or weasels that have killed rats recently: the rat-bite heals slowly, and after an incubation period of from two to four weeks the patient begins to suffer from a series of acute febrile attacks at fairly regular intervals of a few days. These attacks recur for from two to ten months in different instances (Fig. 579). The onset of each is abrupt, with headache,

Fig. 579.—Temperature chart in a severe case of rat-bite fever; only part of the chart is shown; the recurrent attacks extended over a period of four months.

fever up to 102–106° F., malaise, pains all over, often a rigor, severe pain and swelling in some of the muscles, recurrence of inflammatory phenomena, rarely suppurative, about the original wound, and urticarial, measly, patchy erythematous rashes on the face, limbs, and trunk. Each attack lasts for a day or two, the patient being fairly well in the intervals; during the attack a varying leucocytosis is common. Rat-bite fever is not fatal: it is due to infection by a spirochæte; and the disease is generally stopped at once by a single injection of salvarsan or one of its equivalents. A. J. Jee-Blake.

RINGWORM. (See FUNGUS AFFECTIONS OF THE SKIN, p. 309.)

RISUS SARDONICUS is the fixed unmirthful grin that results from spasm of the muscles of both sides of the face. The angles of the mouth are drawn outwards and the eyelids raised by tonic contraction of the same muscles as produce the facial expression of smiling, but the spasm is maintained in a way that at once excludes natural smiling.

The chief causes of the condition are *tetanus*, *strychnine poisoning*, *malingering*, *hysteria*, *cataplexy*.

1. **Strychnine Poisoning and Tetanus** are the two chief causes of typical risus sardonius. The main point to rely on in distinguishing the two is the history, if it is obtainable—the injection of an overdose of strychnine hypodermically or the taking of a rat-paste, on the one hand, or the occurrence of some small but penetrating wound by a rusty nail or earth-soiled knife or stick during the fortnight preceding the symptoms, on the other. The absence of any known wound, however, does not exclude tetanus. If lock-jaw and stiffness of the neck are prominent features, tetanus is more probable than strychnine poisoning, and vice versa. In strychnine cases, either the patient will die quickly, or the symptoms will subside rapidly, whereas in tetanus they may persist unabated for several days. In a few instances the diagnosis may only be settled by the discovery of strychnine in the gastric contents, or of tetanus bacilli in anaerobic cultivations from the infected wound.

2. **Malingering** may take the form of imitated convulsions, during which the features may be kept fixed in one position or another, sometimes in that of smiling. The fixed voluntary contractions cannot be maintained long, however, on account of fatigue, so that although there may be some doubt at first this generally disappears soon. The patient is usually a man who has something to gain by malingering: a night's lodging in a hospital, for instance.

3. **Hysteria** sometimes takes a form that may for a while raise doubts as to strychnine having been taken, but, as a rule, the multiformity of the contortions points to the correct diagnosis. The features may be kept fixed for a time, but sooner or later they become twisted into all sorts of shapes, and the tonic and clonic spasms of the body and limbs are not in any way regular, as they are apt to be in strychnine poisoning and tetanus. The patient is likely to be a woman, and there may be a history of previous hysteria. During a quiescent interval it may be found possible to stroke or touch the patient without bringing on a convulsion, whereas in strychnine poisoning and in tetanus the slightest touch is apt to evoke a violent and generalized spasm, even opisthotonos.

4. **Cataplexy**. The differential diagnosis is not, as a rule, difficult. A cataplectic case is chronic; the facies is by no means always that of smiling, but if it should be, then the smile is a fixed one; the chief characteristic of the condition is the maintenance for hours at a stretch of some attitude that would rapidly fatigue an ordinary person; the history and the associated mental symptoms of melancholia or dementia point to the diagnosis, and tetanus and strychnine poisoning would be excluded by the absence of tetanic spasms.

It only remains to add that a few cases of *facial sclerodermia* may simulate risus sardonius, though more often there is complete smoothness of the features and lack of expression. There are no spasmodic contractions, the condition comes on gradually, is permanent, and the diagnosis becomes obvious at once when the hard smooth skin is palpated, for one cannot pick it up between one's fingers. *Herbert French.*

RUMINATION. (See MERYCISM, p. 485.)

RUPIA. (See SCABS, p. 742.)

SACRALGIA. (See PAIN IN THE PELVIS, p. 572.)

SALIVARY GLANDS.—(See SWELLING OF THE SALIVARY GLANDS, p. 848.)

SALIVATION, UNDUE. (See PTYALISM, p. 660.)

SAND, INTESTINAL. This is seen in the motions, especially when they are fluid and the patient has membranous colitis. It is like the finest sea-sand; its colour varies owing to varying degrees of imbibition of faecal pigment. Usually it is red, looking something like fine uric acid, and it varies from this to a pale dirty yellow. It is seen best showing up against the white of the bed-pan in which it lies. Analysis shows that it consists of from 30 to 70 per cent of organic matter, doubtless all derived from the feces. The inorganic matter is invariably nearly all calcium phosphate, with traces of calcium

oxalate, magnesium, iron, and perhaps silica. The amount of sand passed in a day may be four teaspoonfuls, but usually it is much less. Many patients pass it for years, but not always constantly even then; it may be passed daily for weeks, and then for weeks none is passed. It is far commoner in those who have membranous colitis than in other patients, but it has been seen with malignant disease of the large intestine. It must be distinguished from false intestinal sand, which looks very like it and may be found in the motions of those who have eaten largely of pears; this is entirely vegetable, and can be distinguished easily from true intestinal sand by microscopical examination.

W. Hale White.

SCABS.—The scab, or crust, one of the secondary cutaneous lesions, is a more or less irregular, dried-up mass of exudation on the surface of the skin. It may be produced by the desiccation of serum, pus, or blood, or of a mixture of these fluids, and commingling with these substances there may be epithelial débris, or fat, or fungous elements. Scabs form on matured vesicles, bullæ, and pustules, on ulcerations, erosions, and on every kind of excoriation, pathological or traumatic. If the exudation is thin as in eczema, they are soft and friable; if it is thick, they may be tough and adherent, and successive layers may be formed, as in the rupial crusts of syphilis. Scabs composed largely of fungous elements are more or less friable, and these, like those resulting from the seborrhæic process, may partake of the character of scales as well as of scabs. Such formations, however, as for example the 'crusts' of favus, are in the nature of scales rather than of scabs, and are noticed elsewhere. (See FUNGUS AFFECTIONS OF THE SKIN, p. 309; and SCALY ERUPTIONS, p. 744.)

Scabs vary greatly, not only in consistence, thickness, and adhesiveness, but also in colour and in form; and by attention to these differences the diagnosis of the affections in which they occur may be assisted. Some guidance may be obtained from the condition of the surface from which the scab has been removed; it may be dry when the scab has been long adherent, as in some cases of impetigo; excoriated as in eczema; or ulcerated as in rupia; but the clinician will be guided much more by the primary than by any secondary lesion, and for the decisive diagnostic features of the diseases about to be mentioned the reader is referred to the articles MACULES (p. 477); VESICLES (p. 913); BULLÆ (p. 123); PAPULES (p. 597); NODULES (p. 500); and PUSTULES (p. 681).

In *irritative herpes* the vesicles shrivel up and form yellowish-brown crusts, which after a few days become detached, as a rule leaving no scar but only a brownish stain which slowly fades away. In *herpes zoster* most of the vesicles which do not abort reach the same termination; but others, instead of drying up, burst and discharge a fluid which forms yellowish or brownish crusts; a scar is produced if there is secondary infection and destruction of the deeper layers of the skin, but not otherwise. In *erythema multiforme* there is often considerable scabbing, as is mentioned under VESICLES (p. 919). In *eczema* the lesions may dry up either into scales or into crusts; crustation is usually the third stage in the evolution of the disease, the discharge from the vesicles drying into greyish-yellow scabs of varying thickness, which become detached and are succeeded by others until the 'weeping' ceases. When the lips are attacked they may become so stiffened under layers of crusts superimposed one upon another that the patient can hardly move his lips without fissuring the skin; the 'bathing-drawers' area may be so covered with crusts that the patient cannot walk or sit down without breaking them, and the scabs may be marked by much foulness. One of the characteristic features of what is called *papular eczema* is the appearance of a tiny dome of blood-crust on the papules, due to scratching. In *seborrhæic eczema* there may either be scaling, or the squames may be massed into fatty crusts (see SCALY ERUPTIONS, p. 744). The scabs in *eczema rubrum* are extremely thin, like goldbeater's skin; when they are torn off, a red, wet, raw, tender surface is laid bare. The crusts of *scabies* may be distinguished from those of eczema by their being isolated and distributed irregularly, instead of being grouped, and by the multiformity of the lesions with which they are mixed—vesicles, bullæ, pustules, hæmorrhagic scabs, etc. In most itching diseases there will be found blood-scabs, resulting from the scratching to which the patient is provoked.

In *cheiropompholyx* the bullæ into which the little sago-grain vesicles run dry up into crusts, the removal of which reveals a surface that is red and exquisitely tender. The

appearance and sensitiveness of the underlying skin, together with the limitation to the hands and feet, and often to the hands alone, will help the diagnosis. The crusts of *syccosis vulgaris* also have a limited distribution: they may be confined to the upper lip, and in any case they do not extend beyond the hairy parts of the face; they are brown or yellow, thin, and adherent.

In *impetigo contagiosa* the scabs which are formed from the dried-up fluid discharged by the pustules on rupture are yellowish, but they may be greenish, brown, or even black. A characteristic feature is that they have around them no hyperæmic halo, but look as if they might have been stuck on artificially. In the severe form of the disease styled *ecthyma*, however, the flat irregular scab formed from the ruptured vesicles is surrounded by a more or less pronounced areola. At first loosely attached, the scabs in *impetigo contagiosa* afterwards become so firmly adherent that their removal requires some force and gives rise to a little bleeding. In this affection there is what may be called a secondary scab, formed by the drying-up of the thick, purulent discharge—honey-like in consistence and appearance—from the surface left raw by the removal of the earlier crusts. The reddish stain that appears when the lesion heals is not permanent. In *pemphigus vulgaris* the crusts into which the bullæ shrink are brownish-yellow; and when they fall off spontaneously the surface beneath is not raw, as in *impetigo*, but is covered with newly-formed epidermis, at first purple, afterwards turning brown, and gradually becoming normal in colour. When the area covered by the scabs is extensive there is an unpleasant sense of tension, and, if they are removed prematurely, excoriation may be caused. In the more serious affection known as *pemphigus foliaceus* the crusts are yellowish, and as the disease proceeds large scales are formed. In *pemphigus vegetans* the foul-smelling secretion from the patches of affected skin forms a thin crust which can be stripped off easily, when a papillary excrescence, partly covered with a thin stratum of epidermis, is revealed. The process usually ends in gangrene and death. The excrescences are distinguishable from the condylomata of syphilis by always being surrounded by a zone of bullæ, while condylomata have an infiltrated border.

In *nerve leprosy* the bullæ, which have the same characters as those of *pemphigus vulgaris*, form, on rupture, a large crust, the removal of which exposes a grey surface consisting of altered rete, the epidermis being cast off by suppuration. In this way a succession of yellow scabs or crusts may be formed and fall off, leaving at last a granulating surface which is converted ultimately into a white scar. If the bullæ abort they are followed by a parchment-like scale instead of a crust, and this in turn gives place to a hyperæsthetic ulcer. The scabs of nerve leprosy have some resemblance to the *rupial crusts* of secondary syphilis, but there is little danger of confusion between the two. The rupial crusts, greenish or blackish, consist of several successive layers, each smaller than the one immediately below it, so that a pyramidal structure is formed, somewhat resembling the shell of a limpet. This very characteristic crust, which can scarcely be mistaken for that of any other condition, and distinguishable from the psoriasis rupioides of McCall Anderson by the base being ulcerated, is formed from pustules usually, but may follow also on the drying up of bullæ. The scabs in *secondary yaws* form upon the yellow heads of large papules, and beneath them are found reddish raspberry-like granulations which secrete a little pus, and after a time become pale or even white. Healing usually takes place beneath the scabs, which fall off about the end of the second month from the onset of the secondary rash. The raspberry-like granulations, the characteristic lesion of yaws, will obviate confusion between these crusts and those of any other affection. The crusts of *lupus vulgaris* are greenish-black, like rupial crusts, but they do not consist of layers superimposed upon each other, and dotted around the ragged edge will be seen the 'apple-jelly' nodules which are characteristic of lupus.

In *small-pox* the formation of scabs on the pustules begins in the centre and causes a secondary 'umbilication': it is generally attended by intense itching. In from three to four weeks from their appearance the crusts fall off, leaving a reddened surface, made uneven by scars or 'pits'. The true nature of the disease will have been discovered, even in doubtful cases, before the crust stage is reached. (For the differential diagnosis, see under PUSTULES, p. 681.) In the diagnosis of *ulcers*, the crust is of little importance; these are dealt with under ULCERATION OF THE FACE (p. 891); ULCERATION OF THE FOOT (p. 892); and ULCERATION OF THE LEG (p. 893)

Ernest Dore.

SCALY ERUPTIONS.—The squame, or scale, one of the secondary cutaneous lesions, is a dry, and as a rule laminated, exfoliation of the epidermis. Disregarding the slight, imperceptible desquamation which is a purely physiological process, scales may be said to result either from inflammation, as in psoriasis and pityriasis rubra pilaris; from an abnormal dryness of the skin, as in dry seborrhœa and keratosis pilaris; or from an earlier acute hyperæmia, as in scarlatina and other erythematous eruptions. The process may consist in an over-multiplication of the epidermic cells or in interference with the normal horny transformation. In colour, scales are ordinarily white or grey, either dull and lustreless, as in seborrhœa, or silvery, as in psoriasis; but they are sometimes a dirty yellow, as in some dry syphilides, or even reddish-brown, as in oily seborrhœa. They may be large and thin, as in pityriasis rubra, or small and branny, as in tinea versicolor; even in the same affection (e.g., pityriasis rubra) they may vary greatly in size in different regions. They may consist of a single layer, as in squamous eczema, or of several adherent strata, as in psoriasis. In quantity they may be inconsiderable, as in tinea versicolor, or most profuse, as in psoriasis, pityriasis rubra, and dermatitis exfoliativa. Usually they are dry and friable, but if mixed with an oily secretion, as in seborrhœa, or with a serous or seropurulent discharge, as in eczema, they may partake of the nature of both scales and crusts; except in a few diseases of which they form a highly characteristic manifestation, such as seborrhœa, psoriasis, and pityriasis rubra, they have little diagnostic value, and, as said elsewhere of scabs, diagnosis must usually rest upon primary rather than upon secondary lesions.

Sometimes there is scale-formation in eruptions due to the internal administration of such *drugs* as quinine or belladonna, or to the external application of carbolic acid, iodine, etc.; but it has no significance in diagnosis. In *keratosis pilaris* (xeroderma) and other forms of *ichthyosis* there is always more or less desquamation of the dry and roughened and sometimes warty skin; but here also it is without diagnostic import. Of the scales of scarlet fever, measles, German measles, and other *infectious fevers*, again, nothing need be said, for the diagnosis ought to have been settled before they appear. Nor need the scalliness of tinea tonsurans, tinea versicolor, and other *fungous affections* be referred to here, for the differential diagnosis of these diseases has been given under FUNGUS DISEASES (p. 309). The scales of papular syphilides, again, have been described under PAPULES (p. 597), and the diagnosis of the lesions, both primary and secondary, from those of psoriasis will be found in that article. In the unusual instances of *urticaria* in which desquamation is present, it is so slight as to be negligible. In most forms of *erythema* scales occur; but here again they have little significance for the diagnostician, and it will be sufficient to say that in erythema simplex the desquamation is slight, and that in erythema scarlatiniforme it is more considerable. In *lupus erythematosus* the central scar-like depression of the primary eruptive lesions may be covered either with thin, papery, greyish scales, or with a firmly adherent scab. In parts furnished with sebaceous glands the skin will usually be covered with small adherent scales of sebum, such as at the margin of the patch plug the dilated orifices of the glands, so that numerous comedones are formed. From other forms of erythema, as also from ringworm, lupus erythematosus may be distinguished by the slowness and persistence of the process. The lesion itself, atrophic in the centre, with a well-defined red border, and studded with plugs, can scarcely be mistaken when it appears on its site of election, the face. When, however, it occurs on the hands, it may mimic chilblains so closely that only the lapse of time can make the diagnosis certain, lupus erythematosus being much more obdurate to treatment, and not disappearing in the summer. For the diagnosis between lupus erythematosus and psoriasis, see below; for that between lupus erythematosus and lupus vulgaris, see under NODULES (p. 500).

We now come to affections in which scales play a more important part. In *seborrhœa sicca* (pityriasis alba) there is an exfoliation of epidermic scales mixed with a certain amount of sebaceous secretion. In *seborrhœa oleosa* there is an abnormal predominance of the oily part of the sebaceous secretion, which dries into yellowish or reddish-brown cakes of greasy scales, often with a hyperæmic base and a fringe of papules about the edge. In the face, oily seborrhœa is more often met with than the dry form; but seborrhœa generally, though it may occur on the trunk and limbs, almost invariably begins on the scalp. When not limited to the scalp, as usually it is, it spreads downwards

to the face, round the neck, the chest, the centre of the back, and the limbs. In the light of this preference for the scalp, and the downward extension when the affection is not confined to that part, a typical case of seborrhœa is unmistakable. In cases of seborrhœa which resemble psoriasis, guidance may be found in the scales, which in the latter affection are silvery, and harder. The respective starting-points of the eruptions, however, furnish a safer indication, psoriasis almost always appearing first on the elbows and knees and spreading upwards.

In typical *eczema*, scaling forms the final stage of the pathological process. After the initial erythema comes the exudation, then the crustation (see SCABS, p. 742), next the dry stage, and lastly the desquamation, the epidermis being shed in scales that become progressively thinner and smaller until only a brownish stain is left to mark the site. All the stages are often present at once in a given case. Scaling is frequently a noticeable feature when there is a predominance of erythematous lesions, but it is in *seborrhœic eczema* that this phenomenon is most prominent, the process being followed by the agglutination of epidermic scales which are thrown off in the form of large lamellæ. In some cases the scales may increase in quantity: in others, as is mentioned under SCABS (p. 742), they may become massed into fatty crusts among the hairs. The differential diagnosis of *eczema* has been set out in the articles on the primary lesions. The secondary lesions in this affection may indeed be rather a hindrance than a help in determining its true nature, and in doubtful cases the first thing to do is to remove both scales and crusts in order that the underlying lesion may be examined carefully. As between *eczema* and psoriasis, however, just as between *eczema* and seborrhœa, the scales afford guidance in the diagnosis: while in psoriasis the lower layers of scales are whitish or silvery and hard, in *eczema* they are yellowish, dull, and friable.

In *psoriasis* the scale has distinct diagnostic value. It enters, indeed, into the definition of the disease as an affection of the skin characterized by flat, dry, reddish or red-brown patches of varying extent, covered with whitish, silver-grey, or asbestos-like scales. The scaliness may vary from a thin film to a dense, heaped-up mass. If the scales are removed, a smooth, dry, shining hyperæmic surface is seen, studded with spots that show various gradations of colour, from a deep to a bright red, the bright-red points being the tops of inflamed papillæ. The eruption appears as papules of pin-head size, at first red, but becoming white as the scales form. Spreading centrifugally, the papules form patches, generally roundish or oval when small, and becoming more irregular as they grow larger. They may remain stationary for a long time, and slowly disappear, or, continuing to spread, may become confluent. While the disease is active the individual patch is encircled by a narrow zone of redness, but when it is not spreading this fades away. Sooner or later involution takes place, and the redness which the lesions leave behind them soon disappears, though in protracted cases a brown stain may persist, and in rare instances there may be superficial atrophy. The malady may come and go, recrudescing after nearly disappearing, for the greater part of a patient's life. It is often most abundant when the patient is in the best health, and may almost or quite disappear during serious illness. In distribution, psoriasis is almost invariably symmetrical. Like small-pox, it shows a marked predilection for surfaces that are exposed to friction. Almost always it starts on the tips of the elbows and the fronts of the knees. After the extensor aspects of the limbs, its favourite site is the hairy scalp, and then the trunk, especially over the lumbar region. In typical cases the clinical picture—the patches with sharply defined border, covered with hard, shiny scales: the hyperæmic surface beneath, dotted with red points; the distribution as just described; and the absence of exudation—scarcely admits of misinterpretation. In all these particulars psoriasis differs from *eczema*, as well as in the less intense and less constant itching by which it is attended. On the scalp, while psoriasis usually occurs in patches and ends abruptly at or only just beyond the margin of the hair, seborrhœic *eczema* almost invariably extends over the whole surface, and often involves the face and the neck. Almost always, too, psoriasis spreads upwards from its sites of election, seborrhœic *eczema* downwards from the head. In very chronic forms of *eczema*, in which there may be no history of 'weeping', the diagnosis from psoriasis may be difficult. In all doubtful instances, gentle scratching on the affected surface will bring out the silvery scales if the case is one of psoriasis. The disease shows a special predilection for those who have blue eyes and fair hair.

The papular stage of *lichen planus* may be mistaken for psoriasis. In lichen planus, however, the eruption shows a preference for the flexor aspects of the wrists and knees; it consists of shining-smooth papules, without scales; the ground-tint is bluish-red or violet; and the patches are formed by the aggregation of a number of papules instead of by centrifugal extension. In doubtful cases the whole body must be searched for the typical lesions of either disease.

Lupus erythematosus differs from psoriasis in that in the former condition the patches are generally limited to the face, scalp, ears, and fingers; the scales are adherent and of a greyish tint like mortar and not silvery, the edge of the patch is more elevated, the cheeks or the nose are usually attacked, as they are not in psoriasis, and there are the distinctive plugs in the orifices of the sebaceous ducts. Scarring, too, may be found in the patch, and there may be atrophy of the ears or other parts affected; psoriasis never causes such scarring or atrophy.

As between psoriasis and *papular syphilides*, the diagnosis is given under PAPULES (p. 597). The heaped-up crusts of the condition which has been styled psoriasis rupioides can be distinguished from the rupial lesions of syphilis by the base being ulcerated in the latter disease; but syphilis mimics everything, and cases sometimes occur in which it can be distinguished even from so distinctive an affection as psoriasis only by attention to the history, by the discovery of other lesions, the presence of cachexia, the influence of salvarsan, iodides, and mercury, or by the Wassermann serum test.

In *pityriasis rubra* the whole cutaneous surface is inflamed and reddened, without infiltration or thickening, but accompanied by profuse desquamation, branny on the head, larger flakes from the trunk, huge scales from the hands and feet. Pityriasis rubra may occur as an independent disease—an extremely rare event—or may follow in the wake of erythema multiforme, eczema, psoriasis, lichen planus, dermatitis herpetiformis, and certain drug eruptions. Its most frequent precursor is psoriasis. The constant and profuse desquamation, the papery scales and sheets in which the epidermis is shed, are important diagnostic signs; others are the vivid redness of the eruption, the rapidity with which it is diffused, its universality, the serious impairment of health sometimes issuing in death—and the frequent absence of itching. From eczema it is distinguished by the absence of exudation and of crusts; from psoriasis by its rapid spread and universal diffusion; from pemphigus foliaceus by the absence of loose bullæ and of foul-smelling discharge, the less severe general symptoms, and the greater amenability to treatment; from lichen ruber planus by the absence of papules, as well as by its rapid extension and involvement of the whole area of the body.

The essential lesions of *pityriasis rosea* are patches or circles, very slightly raised and thinly covered with small scales. The eruption usually shows itself first on the abdomen, though it may begin on the chest, back, or limbs. It spreads less rapidly than pityriasis rubra, but in two or three weeks the trunk and the limbs may be covered, and though occasionally it is universal, it seldom extends below the elbow or the knee. The diagnosis is seldom in doubt, the characteristic 'herald patch' with which the rash begins, the red tint, the slight elevation of the patches, the mingling of macular and circinate lesions, the slight degree of scalliness, and the spontaneous involution, forming a distinctive ensemble. The differences it presents from pityriasis rubra have been indicated above. From psoriasis it is differentiated by its less inflammatory character, the more rapid onset, the slight scalliness, its neglect of the situations most vulnerable to attack by psoriasis, and the absence of hyperæmic spots on the surface beneath the scales. From seborrhœa corporis, by the dryness of the scales, its much less chronic character, the lesions disappearing spontaneously in a few weeks. From tinea circinata, by the large number and wide distribution of the lesions, and microscopically by the absence of the fungus which is the cause of cutaneous ringworm. From the maculo-papular syphilide, by the absence of infiltration, the lighter colour, the fact that the palms of the hands are usually spared, the lack of concomitant syphilitic signs, and the absence of a positive Wassermann reaction.

Pityriasis rubra pilaris may appear in the form of scaly patches, resembling psoriasis, on the palms and soles, or as a dry eruption, covered with eczematous-looking crusts; but the papule which soon appears is a more characteristic lesion, and the diagnosis of the condition from psoriasis and other affections will be found under PAPULES (p. 599).

SCLEROTICS, BLUE. (See FRACTURE, SPONTANEOUS, p. 304.)

SCOLIOSIS. (See CURVATURE, SPINAL, p. 191.)

SCOTOMATA. (See VISIONS, DEFECTS OF, p. 920.)

SCROTAL SORES. (See SORES, SCROTAL, p. 767.)

SCROTAL SWELLING. (See SWELLING, INGUINO-SCROTAL, p. 833; and SWELLING, SCROTAL, p. 848.)

SCROTUM, SURFACE AFFECTIONS OF THE. Diseases of the scrotal contents are discussed elsewhere, but there are several cutaneous affections which deserve notice. The skin of the scrotum may, of course, be involved in any generalized or widespread eruption, such as that of an exanthematous fever or exfoliative dermatitis, or it may be attacked in common with some other parts of the body in eczema or psoriasis, or again it may be the only region of the body affected. Owing to the heat and moisture and mobility of the skin of this part and its liability to become chafed from clothing, trusses, etc., or irritated by urine or faeces, *intertrigo* and *acute eczema* are common affections of this part. Intertrigo begins as a simple erythema: the skin becomes of a deep-red colour, and gives rise to a gummy exudation which may become purulent, and distinguishes it from a chronic eczema in which the skin is dry, thickened, and covered with branny scales. Eczema is often difficult to distinguish from ringworm (*eczema marginatum*), but the latter nearly always affects the neighbouring skin of the groins, has a well-defined wavy edge, and shows mycelium when the scales are examined under the microscope. *Erythrasma* occurs as a discoid patch or patches of a brownish-red colour covered with fine scales. Unlike *tinca cruris*, these do not undergo involution in the centre, are uniform in appearance, and have no vesicular margin. Under the microscope a very fine mycelium can be identified. In *psoriasis* of the scrotum the skin is dry, and covered with flaky scales: there is less itching, and generally it is associated with psoriasis in some other part of the body.

Syphilis gives rise to moist papules or gyrate erythematous patches or serpiginous ulcers: the whole of the scrotal skin is not affected as in eczema, itching is absent, and the Wassermann test will be positive. Hard and soft *chanere* may affect the scrotum as well as other parts of the genitals: their differential diagnosis is discussed in the section SORES, SCROTAL (p. 767). Boils, warts, sebaceous cysts, and epithelioma are referred to under SWELLING, SCROTAL (p. 848).

Tuberculous ulceration is generally secondary to testicular involvement, and the ulcer will be indolent, with thin undermined edges, contrasting with the clean-cut edge and sloughing surface of a breaking-down gumma. In the rare cases in which the skin of the scrotum is affected by *Paget's disease*, the ulceration is superficial and the ulcer has a well-defined spreading edge with a red granular surface.

Oedema of the scrotum may occur in association with any acute inflammatory process or as part of a renal oedema, or be due to lymphatic obstruction as in elephantiasis: the differential diagnosis is based on factors discussed in other articles. Ernest Dore.

SENSATION, SOME ABNORMALITIES OF. The abnormalities of sensation met with in disease are as numerous as they are important for the purpose of diagnosis. Under PAIN IN THE FACE (p. 518); PAIN IN THE UPPER EXTREMITY (p. 543); and PAIN IN THE LOWER EXTREMITY (p. 538), the question of subjective pain in relationship to diagnosis has been discussed, and reference will be found on p. 545 to another subjective abnormality of sensation to which the term 'acroparæsthesia' is applied.

Wherever sensory loss occurs, it should assist in forming a conclusion as to the site of disease, even if it does not indicate clearly anything with regard to its nature. In order that the sensory loss may give the necessary information, it is absolutely necessary that the physician should ascertain both the limit and the nature of the loss. He will then be able to judge from the shape and locality of the anæsthetic area whether it conforms to a lesion of a peripheral nerve, a spinal root, or some part of the central nervous system. Analysis to show whether the loss is uniform to all forms of sensory stimuli, or whether

it is limited to one or two forms only, will provide additional information for diagnosing the situation of the lesion. In order to utilize the information provided by the shape and size of the area of anæsthesia it is necessary to know what are the areas on the surface of the body which correspond to the distribution of peripheral nerves on the one hand, and of spinal segments or spinal roots on the other. The accompanying diagrams (*Fig. 580*, and *Fig. 584*, p. 751) supply this information to some extent, but in order that it may be used to the best advantage it is necessary to say a few words about various forms

Fig. 580.—The distribution of sensory nerves in the skin.

of sensory loss due to lesions in different parts of the nervous system. Before entering upon this part of the subject, we may explain the way in which we propose to use the terms anæsthesia, analgesia, and thermo-anæsthesia.

Anæsthesia denotes impairment or loss of the cutaneous sensibility to cotton-wool touch, and it is important to remember that parts which are hairless should be chosen for accurate examination.

Analgesia refers to impairment or loss of pain-sense, the adjective 'superficial' being applied when the surface pain produced by the prick of a pin is interfered with, and the

adjective 'deep' when the pain usually associated with squeezing the muscles and deeper tissues is no longer appreciated.

Thermo-anæsthesia indicates loss of appreciation of heat and cold; but the inability to distinguish between things which are warm and cool is not always associated with equal loss of sensibility in distinguishing between objects which are ice-cold and really hot.

Disturbances of Sensation in Peripheral-Nerve Lesions. The afferent mechanism of the peripheral nervous system consists of the following three sub-systems:—

1. *Deep Sensibility.* This conveys impulses excited by pressure and by all movements of joints, tendons, and muscles. Painful impulses derived from excessive pressure are also carried by this sub-system. By its means a healthy person is able to recognize not only movements of joints, but also the locality of the stimulus and the direction of the movement. The fibres which conduct these sensory impulses run mainly with the muscular nerves, and are not destroyed by division of the sensory nerves to the skin.

2. *Protopathic Sensibility.* This sub-system responds to painful cutaneous stimuli (pinpricks) and to the more extreme degrees of heat and cold. The appreciation of these stimuli is vague and inexact as to the locality of the spot stimulated.

3. *Epicritic Sensibility.* To this sub-system is due the power of perceiving and locating light touches (cotton-wool), of discriminating between two points applied simultaneously to the surface, and of recognizing the finer grades of temperature called cool and warm.

It has been shown that when a *peripheral cutaneous nerve* is divided the area of epicritic loss is greater than that of protopathic loss; in other words, there is more overlapping of protopathic sensibility than of epicritic sensibility between neighbouring nerve distributions. Thus, if the *ulnar nerve* is divided near the wrist, there is complete loss to touch, superficial pain, heat, and cold, over an area including the little finger and part of the inner edge of the palm of the hand. This is the area of epicritic and protopathic loss. But epicritic loss extends over a wider area which includes half the ring finger and more of the hand (*Fig. 581*). In this area of epicritic loss pain can be recognized but cannot be localized exactly, while light touch is not appreciated, and the discrimination between cool and warm is absent.

Fig. 581. Division of ulnar nerve at the wrist. The dark area represents loss of epicritic and protopathic sensibility. The line indicates the limits of epicritic loss. (After Head and Sherrin.)

Fig. 582. Peripheral neuritis. 'Glove and stocking anæsthesia.' Cotton-wool and pinprick sensibility impaired or lost over the dotted areas. This is associated with hyperalgesia of the underlying muscles.

Consideration of the above points shows how important it is to define accurately the exact nature of any sensory loss, and to be careful that the appreciation of pressure is not mistaken for that of light touch. If tactile sensibility is tested by the observer's finger or with the head of a pin, the results will be vitiated, because pressure sensibility is at once brought into action.

Another important diagnostic point depends on the fact that protopathic sensibility returns some months before epicritic sensibility in the process of regeneration after the division of a peripheral nerve. During the stage of protopathic repair there is often a considerable degree of hyperalgesia in the affected area; that is to say, the pain produced by a pinprick or a scratch is out of all proportion to the nature of the stimulus.

So far we have dealt with the disturbance of sensibility produced by the disease or injury of a single nerve. In the disease known as *peripheral neuritis* the sensory disturbances are very characteristic, and consist of pain, tingling, tenderness, and cutaneous

anæsthesia. Spontaneous pain in the limbs is often complained of, but more important is the intense suffering produced by movements, and especially by handling the limbs or by squeezing the muscles. At the same time cotton-wool touch is often unperceived on the peripheral parts of the limbs, particularly in what are known as the glove and stocking areas (*Fig. 582*). This combination of deep hyperalgesia and cutaneous anæsthesia constitutes an important differential sign between peripheral neuritis and tabes dorsalis, in which superficial and deep analgesia are nearly always associated.

Disturbances of Sensation in Lesions of the Cord. The impulses of the three peripheral sub-systems—deep, epicritic, and protopathic—combine in new groups soon after they enter the spinal cord. Some impulses cross to the opposite side immediately, others cross after running a short course on the same side, and others ascend to the upper extremity of the cord entirely on the side of their entry. This rearrangement may be summarized briefly thus:

1. Impulses of pain, whether excited by cutaneous stimuli or by excessive pressure, run together in the spinal cord, and cross, probably soon, to the opposite side.

2. Impulses of temperature of *all degrees* cross to the opposite side, and are closely associated, but not intermingled, with those of pain: the impulses of heat are also separated from those of cold.

3. Impulses excited by light touch and by pressure, and those which subserve their localization, accompany each other, cross to the opposite side, probably less rapidly than those of pain and temperature, and ascend in a path which is distinct from that of the latter.

4. Impulses subserving the senses of passive position and movement are associated with those of tactile discrimination (compass points) in their ascent of the cord on the same side as their entry. These impulses pass up the posterior columns.

The accompanying diagram (*Fig. 583*) represents this rearrangement of impulses and their course in the spinal cord.

The chief points of practical importance in clinical work to be deduced from the above considerations are as follows: In the first

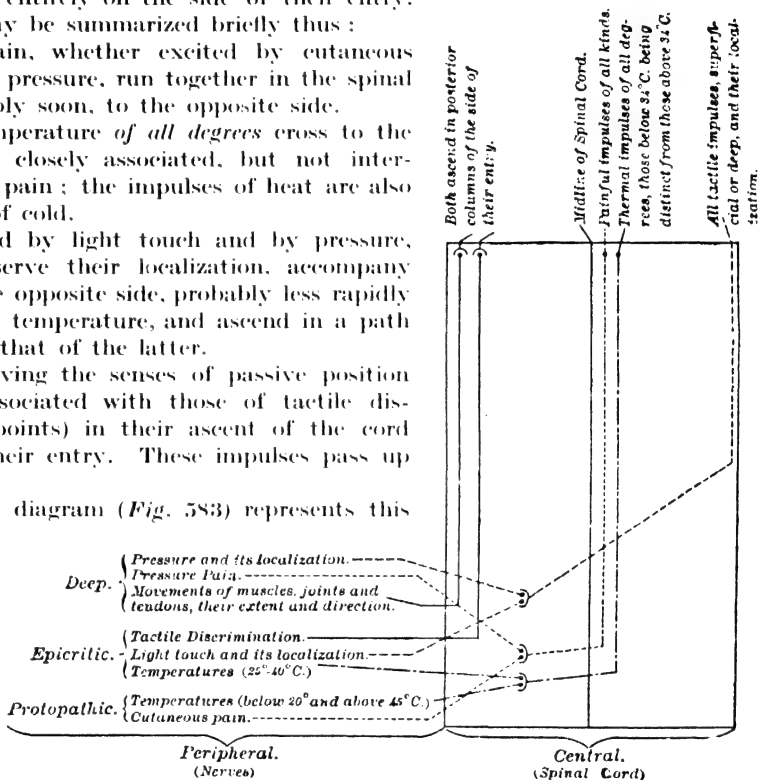

Fig. 583. Diagram illustrating the course of the sensory impulses passing from the peripheral nerves into the spinal cord. (From the author's article in *Oster's Modern Medicine*, vol. VII.)

(1) analgesia result-

(2) from a cord lesion

always includes deep as

well as superficial pain,

and so differs from the analgesia produced by a peripheral nerve lesion, in which, as we

have seen, superficial analgesia may be associated with deep hyperalgesia. Secondly, a

lesion of the spinal cord may abolish the appreciation of thermal stimuli, but, if it

does so, the discrimination between all degrees of heat and cold will be lost. This again

differs from the effect of some peripheral lesions. In the third place, a lesion of the

posterior columns may produce loss of the sense of passive position and movement without

any loss of tactile, painful, or thermal stimuli, a combination which does not obtain as

the result of a lesion limited to the peripheral nervous system.

In all diseases or injuries of the spinal cord, the degree of sensory loss depends, of

course, upon the severity of the lesion. On the other hand, the distribution of the

sensory loss is of the greatest importance for the diagnosis of the level of the lesion.

The distribution must be mapped out carefully, and then compared with the accom-

panying diagram (*Fig. 584*), which shows the sensory areas corresponding to the different

spinal segments.

Secondly, a lesion of the spinal cord may abolish the appreciation of thermal stimuli, but, if it does so, the discrimination between all degrees of heat and cold will be lost. This again differs from the effect of some peripheral lesions. In the third place, a lesion of the posterior columns may produce loss of the sense of passive position and movement without any loss of tactile, painful, or thermal stimuli, a combination which does not obtain as the result of a lesion limited to the peripheral nervous system.

In all diseases or injuries of the spinal cord, the degree of sensory loss depends, of course, upon the severity of the lesion. On the other hand, the distribution of the sensory loss is of the greatest importance for the diagnosis of the level of the lesion. The distribution must be mapped out carefully, and then compared with the accompanying diagram (*Fig. 584*), which shows the sensory areas corresponding to the different spinal segments.

In a case of *myelitis*, for instance, it may be found that sensation is perfect above the level of the umbilicus, and impaired on the trunk and legs below that level (*Fig. 586*). We shall be justified in concluding that the highest point of the disease corresponds to

Fig. 584. Diagram showing the radicular sensory areas of the human body. Compiled by the writer from a study of similar diagrams published by others, and modified in accordance with his own experience. Although the various areas depicted in the diagram are essentially root areas, the information they supply can be used clinically for the purpose of localizing both radicular and intramedullary lesions. It must be remembered, however, that the deductions in the one case are different from those in the other. If, for instance, the character of the sensory change in one of these areas is of the peripheral type, a radicular lesion of the corresponding segmental level may be diagnosed; if, on the other hand, the sensory loss is of the central type in a particular skin area, the spinal lesion must be sought at a level several segments higher than that which corresponds to the sensory area.

For practical purpose, it is important to remember that the uppermost level of sensory change (not the upper level of total anesthesia) should be compared with the nearest corresponding line on this diagram.

If employed with an intelligent appreciation of these points, the diagram is of much clinical importance, but it should not be exploited blindly as a mechanical calculator. Individual variations alone are sufficient to demand a considerable margin of error. (*Copyright. By Dr. E. Farquhar Buzzard.*)

the 9th dorsal segment of the cord. Take another example: *fracture dislocation of the vertebrae* is common in the cervical region, and may crush the spinal cord at the level of the 7th cervical segment. The resulting sensory loss is represented in the accompanying chart (*Fig. 587*).

In testing the sensibility of the skin it is always advisable to work from the anæsthetic area towards the normal, and to note not only complete anæsthesia, but all modifications of sensation. For instance, bordering on the region of complete anæsthesia there may be an area in which the patient is able to appreciate a touch or a pinprick, but in which he describes the sensation produced as differing from the natural sensation elicited by these stimuli. Such modifications should be taken into account in diagnosing the level of the lesion.

Fig. 585.—Committent fracture of the sacrum, with injury to the 3rd, 4th, and 5th sacral roots. Complete loss of sensibility to touch, superficial pain, heat, and cold, resulted in the shaded area.

As a result of disease or injury of one side of the spinal cord, a symptom-complex called *Brown-Séquard paralysis* is met with. This is discussed on p. 608. Fig. 470 (p. 608) illustrates the sensory loss in a case of this kind.

Syringomyelia and *hæmatomyelia* are other conditions in which dissociative anæsthesia is common (Fig. 588). In the former disease thermo-anæsthesia and analgesia are usually found first in the arms and thorax, and they tend to spread all over the body. In rare instances they begin in the legs or on the face. Their distribution is nearly always asymmetrical. The borders of the cutaneous loss are not sharp but shaded off, and correspond to the limits of spinal-root areas. On the other hand, charts sometimes show regions of dissociative anæsthesia which correspond laterally to one or more root areas, but do not cover their longitudinal extent. For instance, the sensory loss in one hand may be limited above by a line encircling the forearm, so as to give it the appearance of a glove distribution. Similarly, on the face a central area, including the nose, mouth, and eyes,

may preserve its sensibility intact, while the surrounding regions are completely insensitive to painful and thermal stimuli. Thermo-anæsthesia and analgesia are sometimes, but not always, co-extensive. Tactile loss also occurs, but usually supervenes in the

Fig. 586.—Dorsal myelitis affecting the cord as high as the 9th dorsal segment. The shaded parts are insensitive to touch, deep and superficial pain, and all degrees of temperature.

Fig. 587.—Fracture dislocation of the cervical spine. The shaded area represents the loss of sensibility to touch, pain, heat, and cold.

later stages of the disease. Subjective sensations may form the initial evidence of the disease, and may be thermal, painful, or tactile. Lancinating pains and cramps are described. More curious are the subjective sensations of drenching sweat in a part which is dry, or of cold in a part which is quite normal in temperature.

In *tabes dorsalis* the disturbances of sensation are numerous and characteristic. Lightning and dull boring pains, tingling, numbness, girdle sensations, and various painful crises are among the subjective abnormalities. Impairment or loss of deep and superficial pain sensibility in various parts of the body is one of the earliest and most important physical signs for the purpose of diagnosis. The cutaneous analgesia is generally found on the legs, and often also in the root areas on the arms and thorax corresponding to the C 8 to D 5 segments (*Fig. 589*). Deep analgesia is nearly always present in the calf muscles. Superficial nerves such as the ulnar may often be found insensitive to rolling or pinching. Delayed sensibility is another phenomenon characteristic of some cases of *tabes dorsalis*. Hyperaesthesia may be present, especially in bands around the abdomen, when gastric or intestinal crises form part of the clinical picture. Intolerance of hot or cold water on any part of the skin is described by some patients suffering from severe forms of the disease. Allocheiria, or reference of a sensory stimulus to the opposite side of the body, has also been observed. The sense of position and movement is nearly always disturbed in locomotor ataxy, and this results in varying degrees of inco-ordination and in the production of Romberg's sign. Astereognosis, or the inability to gauge approximately the size and shape of objects placed in the patient's hand, is another common sensory defect.

Fig. 588. Syringomyelia. The shaded parts show the areas of dissociative anaesthesia, i.e., of thermo-anaesthesia and analgesia. This was associated with atrophic palsy of the upper extremities.

Fig. 589. Early *tabes dorsalis*. The dotted areas represent a characteristic distribution of sensory disturbance. The loss is chiefly of painful stimuli, and the superficial analgesia is almost always associated with deep analgesia.

In *disseminated sclerosis*, sensory troubles do not as a rule constitute so prominent a feature as do motor disabilities, but subjective and objective changes are by no means uncommon. Numbness of one limb lasting a few weeks or months, girdle sensations, and even pains of a neuralgic type, are sometimes complained of. I have known transient hemianaesthesia to be an initial symptom in one case, and astereognosis with loss of sense of position on one side to be the earliest signs of disease in two or three cases. From the diagnostic standpoint these are important facts, because it is very tempting to assume, erroneously, that such sensory phenomena, occurring alone without any reflex or motor signs of organic disease, are hysterical in origin. They are doubtless due to patches of disease near the internal capsule.

This brings us to the consideration of :-

The Abnormalities of Sensation Resulting from Disease of the Higher Parts of the Nervous System. Hemianaesthesia is a common result of the various vascular accidents responsible for *apoplexy* and hemiplegia. It may be present with or without motor paralysis and with or without hemianopia: sometimes all three phenomena are associated in the case of severe lesions of the internal capsule and optic radiations. In most cases of apoplexy hemianaesthesia is slight and transient. Tactile

and pain sensibility may be impaired, usually more so on the limbs than on the trunk, and more especially in the distal portions of the arm and leg. Even when touches are perceived they are localized badly by the patient. With *lesions of the optic thalamus* the opposite side of the body may be the site of a curious sensory disturbance which consists in part of a lowered sensibility to painful stimuli and in part of a great exaggeration of the disagreeable effects produced by such stimuli when they are perceived. For instance, the patient may fail to recognize a light pinprick so well on the affected as on the sound side, but a scratch may produce an intensely painful sensation referred to a very wide area and not localized to the spot stimulated. In such cases the patient often complains also of paroxysms of severe pain in the affected limbs.

The *hemianæsthesia of hysteria* is usually far more complete to all forms of stimulation than any hemianæsthesia due to organic disease of the brain. The hysterical patient is found to have lost taste, smell, and sometimes even hearing, on the anæsthetic side. The visual defect, instead of being hemianopic as in the organic cases, is generally a marked contraction of the visual fields, sometimes amounting to blindness, especially in the eye corresponding to the other sensory defects.

Lesions of the brain-stem may also be responsible for extensive loss of sensation. For instance, thrombosis of the posterior inferior cerebellar artery gives rise to a localized

softening on one side of the medulla, which produces thermo-anæsthesia and analgesia on the same side of the face, and on the trunk and limbs of the opposite side (*Fig. 590*). This sensory disturbance is sometimes complicated by homolateral cerebellar ataxy and cranial nerve palsies.

So far we have dealt chiefly with the various forms of lowered sensibility, and have given little attention to perversions of sensation, such as are indicated by the terms *hyperæsthesia* and *paræsthesia*.

Hyperæsthesia is observed in cases of tabes dorsalis and peripheral nerve lesions as described above, but it is also met with in other conditions of organic as well as functional disease. It is found, for instance, in root areas in cases of vertebral and intravertebral disease. With *spinal caries* and *tumours of the spinal meninges*, a zone of hyperæsthesia may be detected just above the area of anæsthesia produced by the compression of the cord, or it may precede the appearance of compression signs. The increased sensibility is

Fig. 590.—Thrombosis of the left posterior inferior cerebellar artery. The dotted areas show the regions of dissociative anæsthesia, i.e., loss of sensibility to pain and temperature of all degrees.

probably caused by pressure on, or irritation of, the posterior root fibres. A similar phenomenon is a frequent accompaniment and sequel of an attack of *herpes zoster*. The shape and situation of such hyperæsthetic zones afford a clue to the site of the lesion. Hyperæsthesia as well as paræsthesia are among the earliest signs of *subacute combined sclerosis of the cord*, and are referred by the patient to peripheral parts of his four extremities. They may precede by many weeks or months the appearance of ataxic or spastic paraplegia and definite areas of sensory loss. Similar symptoms are also complained of in not a few cases of pernicious anæmia and other severe blood diseases, probably on account of scattered degenerations in the nervous system as the result of the anæmia.

Neurasthenic and hysterical states are responsible for hyperæsthetic areas which have no relation to central or peripheral innervation. In neurasthenia, especially the traumatic variety, the patches are usually found on and around the spine and over the scalp. In hysterical conditions similar patches may be detected in the mammary and ovarian regions.

Hyperæsthesia in connection with *visceral disease* has been referred to in other articles, such as those on PAIN IN THE EXTREMITY (UPPER) (p. 543); PAIN IN THE FACE (p. 548); etc.

A very special peculiarity of sensation, known as Magnan's sign, is met with in sufferers from the cocaine habit : it consists in a subjective feeling as of multiple small worms creeping about under the skin, though in some cases the patient compares his sensation to that of fine sand under his skin.

SKODAIC RESONANCE. When there is a basal and unilateral pleuritic effusion of medium degree the pitch of the percussion note over the upper part of the thorax in front is often higher on that side of the chest on which the effusion is than on the other. It is not a question either of impairment of resonance or of hyper-resonance, but merely of pitch. This higher pitch of the percussion note over the upper lobe, when the lower lobe is compressed by an effusion, is named 'Skodaic resonance', after the observer who first drew attention to it. Its importance is mainly twofold : in the first place it does not indicate disease of that part of the lung which affords the sign—for instance, the fact that, in a case of right-sided effusion, the right upper lobe gives a higher-pitched percussion note than does the left cannot be taken as evidence that there is a lesion, perhaps tuberculous, at the right apex ; in the second place, it is erroneous to suppose that skodaic resonance is obtained only in cases of effusion : its occurrence cannot be taken as proof that dullness at the base is due to fluid there. It is true that *pleural effusion* gives it not only in most marked degree, but also most commonly ; nevertheless it may also be observed in some cases of *basal pneumonia* without effusion, or as the result of compression of a lower lobe by such causes as *subdiaphragmatic* or *hepatic abscess*, *hepatic masses* such as *carcinoma*, *gumma*, or *hydatid cyst*, *great enlargements of the spleen* such as occur in *leukæmia*, a *big heart*, a *pericardial effusion*, or a *mediastinal or pulmonary new growth*.

The cause of skodaic resonance has never been quite decided, and many theories have been propounded about it ; clinically, the most serviceable view is that anything that lessens the degree to which the upper lobe is stretched, yet without actually compressing it, may produce a rise in the pitch of its percussion note. Bilateral compression of the bases of the lungs by such lesions as ascites presumably causes bilateral skodaic resonance, but this is difficult to determine, because the latter is recognizable only when there is a difference of pitch between the two sides.

Skodaic resonance over an upper lobe when there is some lesion affecting the lower lobe on the same side should not be confused with the tympanic note that may sometimes be heard over the other parts of the thorax. Stomach tympany is heard normally external to and below the precordial region over an area known as Traube's space, which is bounded above by the precordial dullness, behind by the splenic dullness, and below by the rib margin. When the stomach is dilated there may be an abnormal extent of this gastric tympany in the thorax. When the transverse colon is distended with gas, or when it is pushed upwards by something intra-abdominal, it may produce abnormal areas of thoracic tympany, particularly in the lower sternal region or on either side of this. Such conditions can scarcely be mistaken for skodaic resonance, for the latter concerns the upper lobe, and is not a definite tympany, but rather a moderate rise in the pitch of the ordinary percussion note, not as a rule obvious till the two sides are contrasted. *Herbert French.*

SLEEPLESSNESS. (See INSOMNIA, p. 401.)

SMELL, ABNORMALITIES OF. Abnormalities of the sense of smell fall into three main categories, namely: (1) *Too great sensitiveness to smells which actually exist*; (2) *Deficient sensitiveness to smells which actually exist*; (3) *Subjective sensations of smells which do not exist*.

1. **Too great sensitiveness to existing smells** is sometimes a nuisance to the individual, but is seldom a sign of disease. There are great differences in the powers of perception of different sensations in different persons, and just as some can appreciate very slight differences in sounds more than others, so can some detect smells that are indiscernible by others. This is natural idiosyncrasy.

2. **Deficient sensitiveness to actual smells** is often but the obverse of the above and no sign of disease, although it may be a detriment to the individual, especially in certain commercial pursuits in which the varying qualities of products are judged partly by smell. When the power of smell, having been normal, becomes deficient or totally absent, the change may affect one nostril only, or both. The condition may be transient or persistent. The commonest cause of transient anosmia is *acute nasal catarrh*, whether the result of an ordinary *cold*, or of other affections such as *hay fever* (coryza e feno), oncoming *measles*, or the effects of drugs such as *iodide of potassium* or *arsenic*.

Persistent anosmia may be due to:

a. Inability to get air freely, or at all, through the nostril, as the result of:

Adenoids	Hypertrophic rhinitis
Polypi	Syphilis
Dislocated nasal septum	Necrosis of bones in the nares
Nasal septal spur	Occluded anterior or posterior nares.

b. Alteration in the olfactory mucous membrane, so that it no longer transmits impulses to the endings of the olfactory nerve, although the airway is free:

Atrophic rhinitis	Paralysis of the fifth nerve, leading to undue dryness of the mucosa.
-------------------	---

c. Abnormalities of the olfactory nerves:

Congenital absence	noxious vapours, ammonia, or snuff;
Hydrocephalus	or part of a general peripheral neuritis
Olfactory neuritis, either the result of over-stimulation locally by strong	Post-influenzal changes
	Old age.

d. Cranial lesions, especially hemorrhage, thrombosis, embolism, softening, injury, or tumour of the uncinate gyrus, which is the centre for smell.

e. General nerve diseases, especially:

General paralysis of the insane	Tubes dorsalis.
---------------------------------	-----------------

f. Hysteria.

There is little need to discuss the above table in detail, for each heading speaks for itself. When a case is being investigated the history is very important: it is next necessary to examine the nose carefully through a speculum, and to test the airway through each nostril: if there is any local lesion it will generally be obvious, and only after local affections have been excluded should conditions in groups *c*, *d*, *e*, and *f* be considered. Anosmia will seldom if ever be a prominent symptom, except in connection with local affections of the nose: when due to any other cause there will nearly always be some other symptoms which will attract attention more than the anosmia itself.

3. **Subjective sensations of smells which do not exist externally** may be due to:

- Offensive or purulent inflammations of the nose or of the air-cells communicating with it, especially empyema of the antrum of Highmore, or of a frontal, ethmoidal, or sphenoidal sinus.
- Local thickening of the meninges, tumour of the brain, or interference with the vascular supply, causing irritation of the hippocampal region.
- An aura preceding an epileptic seizure.
- Hysteria.
- Insanity.

In arriving at a diagnosis, it is chiefly important to exclude purulent affections discharging into the nose; if it is possible to state with certainty that the abnormal sensations have no such organic basis it is not difficult as a rule to decide between the other causes. It is a curious fact that subjective abnormalities of smell are apt to be associated with delusional insanity concerning the genital organs, in which the prognosis is not free from acute dangers.

Herbert French.

SNORING may be a very troublesome symptom in some patients, particularly to those who have to sleep in the same room with them; but it is often less an indication of disease than merely a bad habit. Most snorers sleep with their mouths open, and breathe partly through the nose and partly through the mouth; but it is possible for snoring to occur with the mouth completely shut and nothing the matter with the nasal passages. The tendency is increased, however, by any obstruction of the nasal airway, so that particular examination should be made for such lesions as undue smallness of the nares or a tendency for the soft parts of the nostrils to collapse on inspiration, deflected septum, hypertrophic rhinitis, polypi, adenoids, acute or chronic nasal catarrh, inflammation of the accessory sinuses or of the pharyngeal tonsils, or even a fibrosarcoma or other neoplasm of the nasopharynx.

Herbert French.

SORE FINGER. (See FINGER, SORE, p. 301.)

SORE HEEL. (See PAIN IN THE HEEL, p. 551.)

SORE THROAT may be due to one or other of many different causes:—

1. Affections of the Tonsils:

Quincy

Acute Tonsillitis

a. With reddening and swelling only:—

Acute inflammation due to various micro-organisms, especially to streptococci; staphylococci; pneumococci; pneumobacilli; diphtheria bacilli; Hoffmann's bacilli; Vincent's spirilla and fusiform bacilli; spirochaeta (treponema) pallida; micrococci catarrhales; bacilli influenzae; tubercle bacilli. The sore throats of scarlet fever, rheumatic fever, German measles, and measles are probably not due to specific micro-organisms, but to streptococci, or others of the bacteria just enumerated.

b. With redness, swelling, and exudation:

Follicular tonsillitis due to streptococci, etc., as above

Diphtheria

Vincent's angina

Syphilis

Kirkland's disease, or epidemic cervical adenitis

c. With ulceration:—

Phlegmonous tonsillitis due to streptococci, etc., as above

Syphilis

Vincent's angina

Chronic Affections of the Tonsils:—

Recurrent inflammation often associated with adenoids, or tonsillar hypertrophy, especially in children

Primary or secondary syphilis

Vincent's angina

Squamous-celled carcinoma (epithelioma)

Sarcoma

Gumma

Tubercle

Actinomycosis

Foreign body, such as a fish bone.

2. Inflammation of the Soft Palate, Uvula, and Fauces:—

Catarrh, occurring either by itself or associated with any of the varieties of tonsillitis enumerated above

Gumma

Squamous-celled carcinoma

Tubercle

Actinomycosis

Aspergillosis.

3. Affections of the Pharynx:

Acute catarrhal pharyngitis due to any of the micro-organisms mentioned under the heading of acute tonsillitis

Chronic granular pharyngitis due to smoking in excess; or to over-use, as in clergyman's, costermonger's, or stockbroker's sore throat

Squamous-celled carcinoma of the pharynx

Postpharyngeal abscess

Varicella

Variola.

4. Laryngeal Conditions, especially : —

Acute catarrhal laryngitis due to any
of the organisms mentioned above
Tuberculous laryngitis
Syphilitic laryngitis

Carcinoma laryngis
Acute perichondritis of the arytenoid,
thyroid, or cricoid cartilages
Injury.

5. Sore Throats resulting from the Swallowing or Inhalation of Irritants : —

Corrosives, such as alkalis or strong
acids

Ammonia vapour, chlorine fumes
Hot steam.

6. Mumps.**7. Acute and Subacute Adenitis** of the lymphatic glands in the neck.

Notwithstanding the length of the above list the differential diagnosis of a sore throat in practice is not difficult as a rule. Inquiry into the history and inspection of the parts in a good light will generally serve to give one a shrewd notion of the nature of the complaint. The chief point in practice is to determine as soon as possible whether the Klebs-Löffler bacilli of diphtheria are present or not, for there is no kind of sore throat which can be recognized clinically as non-diphtheritic. It is important that swabbings should be taken from the inflamed parts and examined by a bacteriologist both directly in films stained by Neisser's method or one of its modifications, and by means of cultures. Similar bacteriological investigations will serve to determine which of the organisms mentioned above is responsible for an acute or follicular or ulcerative sore throat other than diphtheritic, it being borne in mind, however, that the organism should be found in fairly pure cultures if it is to be regarded as causative and not merely as a secondary or even casual infection.

Fig. 591. —Ordinary hyperemic sore throat.

Fig. 592. Left-sided quinsy.

1. Affections of the Tonsils.—*Quinsy* (Fig. 592) is practically always asymmetrical, one tonsil being very much more bulged than the other; the surface is reddened, generally without follicular suppuration, and the diagnosis is ultimately confirmed by the bursting of the abscess.

The presence of Klebs-Löffler bacilli in association with a sore throat may be regarded as conclusive proof that the lesion is *diphtheria*, even though there may be no typical diphtheritic exudate (Figs. 593–596). Diphtheria having been excluded, the diagnosis of one of the other varieties of acute tonsillitis is rendered possible. The frequency with which *acute rheumatism* is associated with recurrent tonsillitis, especially in young people between the ages of five and twenty, should always be borne in mind; the patient may or may not have suffered from other effects of acute rheumatism, such as joint pains, endocarditis (evidenced by the bruits), pericarditis, pleurisy, erythema nodosum, chorea; or a history of such rheumatic affections may be obtained in other members of the same family. The tonsillitis is benefited by sodium salicylate, but by no means to the same extent as are

the joint pains, so that the effect of treatment is not by itself conclusive evidence of the nature of the complaint.

When acute rheumatism gives rise simultaneously to generalized erythema and to tonsillitis there will be difficulty in excluding *scarlet fever*, especially if there has been nausea or actual vomiting; in some such cases the diagnosis will be one of opinion only; that which was regarded at first as acute rheumatic tonsillitis and erythema may prove to have been scarlatina after all, should the patient presently develop acute nephritis, or

Fig. 593. Mild diphtheria simulating follicular tonsillitis.

Fig. 594. Diphtheritic sore throat of medium severity.

Fig. 595. Severe diphtheritic sore throat, showing spread of the membranous exudate to the palate.

Fig. 596. Phlegmonous diphtheria.

if other members of the family develop typical scarlatina; the occurrence of extensive peeling of the skin is not conclusive evidence of scarlatinal erythema and sore throat. If the patient is known to have had scarlet fever formerly, the rheumatic nature of the case is more likely.

Follicular tonsillitis (Figs. 597, 598) is not a final diagnosis, for it may be due to various different micro-organisms, and there is no doubt that the diphtheria bacillus may produce that which to inspection presents multiple foci of pus in the different tonsillar crypts formerly regarded as being characteristic of follicular as distinct from diphtheritic tonsillitis. The only conclusive proof that a comparatively simple follicular tonsillitis is not diphtheritic is bacteriological examination. If clinical points alone have to be relied on one would say that the higher the temperature, the greater the

constitutional disturbances, and the more sudden the onset, the more likely is it not to be diphtheria.

In *Vincent's angina* (Fig. 599) the characteristic micro-organisms are elongated fusiform bacilli symbiotic with spirilla (Fig. 609, p. 779). The disease is, as a rule, more resistant to treatment than are other forms of acute sore throat; beginning like a simple tonsillitis with exudation, the condition passes on to more or less severe ulceration associated with faecal odor of the breath, but without the fatal termination that would almost certainly result

Fig. 597.—Mild follicular tonsillitis.

Fig. 598.—Severe follicular tonsillitis.

Fig. 599.—Vincent's angina.

Fig. 600.—Syphilitic sore throat.

from a corresponding degree of diphtheritic or phlegmonous sore throat. The disease cannot be diagnosed with certainty without the aid of the bacteriologist.

Syphilis may cause acute soreness of the throat in its secondary stages, and unless that possibility is borne in mind, one may diagnose as acute simple or acute follicular tonsillitis that which is really syphilitic (Fig. 600). There is more or less pyrexia, and in most cases there will be tenderness of the scalp and of the bones, together with the well-known roseolous eruption upon the skin and the 'snail-track' ulcers upon the pharynx. The diagnosis may be more difficult in women than in men, for in the latter the remains of the penile chancre may still be obvious. Wassermann's serum test may assist materially in the diagnosis of doubtful cases, or the *Spirochæta pallida* may be recovered from the faucial exudations.

Chronic affections of the tonsils in children nearly always result from recurrent acute attacks of non-diphtheritic tonsillitis, generally in association with adenoids, both affections

arising from the habit of mouth breathing. Inspection of the bulging hypertrophied tonsils, with or without digital examination of the posterior nasal fossa, will indicate the diagnosis. In older persons simple hypertrophy from recurrent tonsillitis becomes less common, but persistent infection of the lower pole of one or both tonsils is a state of affairs that is commoner nowadays than it used to be. The patient may be suffering from systemic illness, such as rheumatoid arthritis or anemia, without much complaint about the throat itself; and yet on tonsillar examination cheesy material may be expressed from the lower part of a tonsil in proof of its being chronically inflamed even when there is no particular enlargement of the tonsil as a whole.

In rare instances an actual *chancre* appears upon one tonsil, giving rise, unless secondary symptoms are present, to much difficulty in diagnosis until the case has been watched. *Malignant disease of the tonsils*, whether *squamous-celled carcinoma*, or *sarcoma*, is fortunately not very common; when it does develop, its comparatively non-acute course and its unilateral distribution with progressive ulceration of the central parts and overgrowth of the edges of the neoplasm will point to the diagnosis, though it may be necessary to excise a small part and examine it histologically before one can be sure. A *gumma* of the tonsil is rare, but may at first simulate squamous-celled carcinoma: in case of doubt the Wassermann's reaction would be tested, or a small portion of the suspicious mass might be excised, and examined microscopically: or if operative measures were not to be adopted at once, potassium iodide or salvarsan might be administered, and the lesion would be shown to be gummatous if it were thereby relieved or cured. *Tuberculous ulceration* of the tonsils is uncommon, practically never primary, but nearly always preceded by phthisis or tuberculosis of the larynx. The diagnosis will be indicated by the discovery of tubercle bacilli in the sputum, though it should not be forgotten that carcinoma or gumma might affect the tonsil in a person who has phthisis. *Actinomyces* and *aspergillus* of the tonsils or fauces are both rare; but the diagnosis is overlooked sometimes on account of the requisite bacteriological tests being omitted.

2. Inflammation of the Soft Palate, Uvula, and Fauces.—This may be seen in many cases of common cold; in association with acute rheumatism; in persons who have recently returned to town from a holiday; in patients who have been subjected to the influence of motor-car dust stirred up from the roads after the latter have been dry for about three days—a longer period of dryness seems to lead to relative disinfection of the dust, whilst rain keeps the dust from rising, so that either continuance of fine weather or a return to wet leads to a disappearance of the sore throats; or in those who are subjected to the influence of relatively concentrated microbes, as in the air of old-fashioned hospital wards, of ill-ventilated much-inhabited rooms, of sewers, and the like. Often a rim of acute reddening is to be seen all along the edge of the anterior pillars of the fauces, and affecting much of the uvula and of the soft palate (*Fig. 591*, p. 758), producing, as a rule, but little pyrexia, though much discomfort in swallowing, and a raspy feeling at the back of the mouth on first waking in the morning. This inflammation of the palate and fauces may or may not be associated with tonsillitis, pharyngitis, or laryngitis; it is clearly microbial; and doubtless more than one of the varieties of bacteria mentioned above may produce the lesion. The diagnosis of the fact of inflammation is obvious on inspection; that of the nature of the micro-organism requires skilled bacteriological assistance.

During the last few years a new and common disease, epidemic in character, and with acute sore throat, fever, and enlargement of the upper cervical glands as its main symptoms, has been described by Kirkland, of Cheltenham; it is spoken of variously as *Kirkland's disease*, the *Cheltenham disease*, *epidemic cervical adenitis*, or *glandular fever*. In some respects it resembles diphtheria, in some rheumatic fever, and in some atypical scarlatina without rash, but it differs from all these, and is now regarded as a specific malady. It affects young and old alike, is very infectious, generally occurs in epidemic form, may be mild, medium, or severe, but generally ends in recovery. Starting with sore throat and a rise of temperature to 102° F. or higher, the patient soon complains mainly of extreme tenderness of the neck, and on palpation acute tender swelling of the parotid, submaxillary, and jugulo-facial glands is found; the swelling may be considerable, but it generally resolves without suppuration. Fever may last only a day or two, but in severe cases it may persist for a fortnight, especially if the malady relapses after a period

of improvement as it is apt to do (*Fig. 601*). The tonsils, uvula, fauces, and pharynx may be merely red and injected; or on the other hand there may be an exudation simulating diphtheria. On cultivation of swabbings from the throat no Klebs-Löffler bacilli can be found, but as a rule streptococci in abundance. What is very remarkable is that in most of the cases the heart is affected during the illness, but without producing permanent valvular changes like those of rheumatic fever; the impulse becomes diffuse, the heart dilates, there is often a local systolic mitral or aortic bruit, or both, and the pulse may be both feeble and intermittent. There is seldom albuminuria, but the general toxæmia in

except at the hands of an expert laryngologist : the condition may be acute and apparently spontaneous as the result of local infections analogous to those which produce suppurative periostitis, or it may follow injury—a blow, a throttle grip, an attempted suicide, or an accident : or it may be part of a state termed ‘bed-sore of the larynx’, apt to arise in those who have been lying on their backs ill for a long time, whether from acute conditions such as typhoid fever or from chronic illness of any kind causing bed-riddenness ; or it may be a more chronic type of thing, analogous to fibrositis or rheumatoid arthritis affecting the perichondrial tissues of the larynx.

5. Sore Throats Resulting from the Swallowing or Inhalation of Irritants and Corrosives are diagnosed as a rule by the history : inquiry will generally suffice to indicate that some irritant has been taken, or there may be direct evidence of it in the form of eschars on the lips or the buccal mucosa : there may be vomiting and hæmatemesis ; analysis of the gastric contents may indicate the nature of the poison taken : ammonia may be detected by the smell.

6. Mumps and Acute Adenitis of the Cervical Lymphatic Glands may each produce marked soreness of the throat in addition to dysphagia, stiffness, discomfort, and pain. Mumps is not difficult to diagnose unless its possibility is forgotten, in which case it might be mistaken for acute oedema of the neck or other similar lesions. The way in which the swelling is located in the salivary glands, starting on one side and spreading to both, is often pathognomonic. Cervical adenitis might simulate mumps, but careful palpation will generally enable one to determine that the swelling is not in the salivary but in the lymphatic glands, and it will only remain to decide what has been the source of the infection. This will probably have been from some inflammatory, ulcerative, or malignant focus in connection with the shoulders, neck, head, face, lips, cheeks, gums, teeth, tongue, fauces, uvula, palate, tonsils, pharynx, or nares ; the differential diagnosis will be based upon inspection and palpation of the parts, together with bacteriological examination.

It only remains to add that *scarlet fever* is at the present time so atypical that acute cervical adenitis may really be of scarlatinal origin without any scarlatiniform rash having been observed upon the skin. One would naturally look for evidence of desquamation, sore throat, bald tongue, albuminuria, nephritis, perhaps otitis media : but there is no doubt that some cases of acute cervical adenitis are really scarlatinal without there having been any other sign of this disease except pyrexia and sore throat. A few such cases prove rapidly fatal, and they have recently been recorded as examples of acute and fatal sore throat corresponding to one form of the *angina maligna* of the eighteenth century.

Herbert French.

SORE TONGUE. (See PAIN IN THE TONGUE, p. 590.)

SORES, PENILE. Sores on the penis may be present on the thin mucous covering of the glans or prepuce, or on the cutaneous surface of the body of the penis ; they are more common in the former situation.

Ulceration in the neighbourhood of the glans penis may be due to :—

- | | | |
|------------------------|-------------------------|-------------------------------------|
| 1. Balanitis | 4. Chancre | 7. Tuberculous ulceration |
| 2. Herpes progenitalis | 5. Epithelioma | 8. Injury, for example from a bite. |
| 3. Soft sore | 6. Gummatous ulceration | |

1. Balanitis.—If inflammatory processes have been allowed to continue beneath the prepuce, ulceration and excoriation of the mucous membrane covering the glans penis or lining the prepuce will occur, accompanied by a stinking, purulent discharge. Multiple shallow ulcers are formed, rapidly coalescing and causing considerable discomfort. The prepuce often becomes swollen and oedematous, preventing retraction, so that a condition of phimosis occurs, or, if retraction has taken place, the analogous state of paraphimosis, almost strangulating the end of the penis and even causing it to become gangrenous. Care must be exercised in diagnosing a simple balanitis from one accompanying acute gonorrhœal urethritis or an underlying syphilitic or soft chancre. With an acute urethritis there will be a history of infection, pain along the course of the urethra during micturition, and perhaps chordee : the intracellular gonococcus may be identified in a stained smear of the discharge.

If a chancre exists under the swollen phimosed prepuce there is often a tender spot

about the corona or at the frænum. With a soft sore, consecutive sores may appear about the orifice of the prepuce, whilst the inguinal glands are much more likely to be inflamed or to suppurate than with simple balanitis. A syphilitic chancre obscured by a phimosis can usually be felt distinctly under the skin, and causes a comparatively small amount of discharge, whilst the inguinal glands become enlarged but do not suppurate. The history of the date of infection, Wassermann's reaction, or the subsequent appearance of secondary symptoms, will help materially in diagnosis. Spirochaetes may be found in the discharge.

A form of balanitis which is frequently very obstinate to treatment may occur in patients the subjects of gout or diabetes mellitus.

2. Herpes Progenitalis.—Herpes may attack the genital organs as part of a herpes zoster in which the cutaneous eruption depends upon some lesion of the central nervous system, or as a local affection, the so-called catarrhal herpes. The disease begins as a patch of erythema on the inner surface of the prepuce or on the glans penis, followed by vesicles and pustules; the latter become rubbed by the clothes, and form small ulcers. Herpes of the genital organs tends to recur, so that a previous history of a similar attack is often forthcoming. If seen during the vesicular stage no difficulty will be met with in the diagnosis; but if suppuration has followed, it must be diagnosed from a venereal sore. Soft chancres are usually deeper, with marked edges; their base is sloughing, and they are usually accompanied by a bubo, which is exceptional with herpes. A syphilitic chancre is usually single, indurated, and raised, and is accompanied by the typical multiple, discrete, amygdaloid glands in the inguinal region. It should be remembered that syphilis may become inoculated upon a herpetic patch or that herpes may appear in an area previously inoculated with the syphilitic virus.

3. Soft Sores or Chancroids of the penis occur almost invariably from infection during sexual connection. The incubation period is short, a vesicle occurs in two days, and this breaks down rapidly to form a rounded or oval ulcer with sharply defined edges and a yellowish sloughing base. The ulcers appear usually on the mucous surface of the glans, frænum, or corona, and are most often multiple, direct inoculation occurring from an ulcer to the contiguous part. They may cause rapid destruction of tissue, perforating the frænum or spreading over the surface of the glans. The soft sore must be differentiated from others occurring on the glans, and above all from a syphilitic chancre. At the same time it must be remembered that besides the infection with chancroid, a simultaneous infection with syphilis may have taken place, so that a soft sore may ultimately become indurated and assume the character of a primary syphilitic lesion. The chancroids are multiple, are accompanied by a good deal of thin, purulent discharge, and by a painful swelling of the inguinal glands, usually of one side, which have a marked tendency to suppurate. On the other hand, a syphilitic chancre is nearly always single, is raised and indurated, has little discharge, and is accompanied by enlarged, but firm and indolent, glands in both inguinal regions; the incubation period of a syphilitic chancre is from twenty-one to twenty-eight days. The multiple ulcerations caused by herpes are more superficial, and rarely cause a bubo.

4. Chancre—the initial lesion of syphilis—generally appears on the penis, and is most common in the neighbourhood of the frænum or coronary sulcus. A chancre appears about twenty-five days after infection, as a reddened patch, which becomes raised above the surface of the mucous membrane, with distinctly indurated margins. The central part breaks down into an ulcer, discharging a thin, purulent fluid, and at the same time the inguinal glands of both sides become palpable, slightly enlarged, but discrete, and with no tendency to suppurate. The chancre increases but slowly in size, or may occasionally become smaller without any treatment, and after a further lapse of from four to six weeks the typical secondary symptoms make their appearance; namely, a roseolar rash (*Fig. 383, p. 478*) on the chest, abdomen, face, and thighs, general adenitis, and mucous patches about the faucial pillars and tonsils. The diagnosis of the primary lesion of syphilis frequently presents no difficulties, the indurated character of the sore, the date of its appearance after infection, and the presence of firm, indurated glands in the inguinal region, being distinctive. In other cases the character of the sore is by no means distinctive, and it is necessary to differentiate it from other lesions of the penis. Careful search must be made for the *Spirochaeta pallida* in the serum expressed from the sore for definite evidence of syphilis, but too much reliance should not be placed on a negative Wassermann

reaction in the early stage of the disease. If the sore be syphilitic, the secondary manifestations of the disease will follow, provided that the doubtful ulcer is not treated as a chancre. Thus, in any case in which syphilis is suspected, but not wholly certain, it is advisable to withhold any specific treatment for syphilis until such time as secondary symptoms appear, so that a patient may not be condemned to the lengthy process of treatment for syphilis until the diagnosis is absolutely certain.

A chancre may be simulated by an inflamed soft sore, especially if the latter has undergone cauterization. Soft sores are, however, frequently multiple, appear within a few days of infection, and are accompanied by painful enlargement of the inguinal lymphatic glands, which are particularly prone to suppurate. It must not be forgotten that a double infection may have occurred, so that a soft sore may show little inclination to heal or, becoming indurated, may present the features of a chancre after about three weeks, followed later by the symptoms of constitutional syphilis.

Epithelioma of the penis in the early stage may be confused with syphilitic chancre. In epithelioma there is no history of infection: it occurs only in elderly patients, and there is frequently a greater destruction of tissue than in syphilis. The inguinal glands are not enlarged until the sore has been present for some weeks, and there are no secondary lesions such as the faucial ulceration and cutaneous rash. If any doubt exists, a small piece may be removed from the edge of the ulcer for microscopical examination.

Perhaps the greatest difficulty in the diagnosis of a chancre is experienced when the latter is hidden beneath an inflamed and phimosed prepuce. There is a purulent and foul discharge from beneath the oedematous and swollen prepuce: the inguinal glands are enlarged from the associated sepsis. If a chancre is present, it can frequently be felt as an indurated area under the prepuce, whilst if it has been present for some time, the secondary lesions of syphilis may be present. If any doubt exists in an elderly patient as to whether an indurated subpreputial area be an early epithelioma or a syphilitic sore, the prepuce should be split up along the dorsal aspect under anaesthesia, the ulceration inspected, and a small piece submitted to microscopical examination if necessary.

5. **Epithelioma** (squamous-celled carcinoma) is the most common form of malignant growth of the penis. It arises most frequently from the inner aspect of the prepuce, or from the mucous membrane of the glans, as a small, raised ulcer, with friable, irregular edges. It is rarely present before the age of forty, and frequently occurs on the site of previous ulceration or long-standing irritation. An epitheliomatous ulcer increases in size gradually in spite of various forms of treatment, and with it is frequently associated glandular enlargement in the inguinal area. At first the glands may be enlarged from septic infection, but later from malignant infiltration. An epitheliomatous ulcer may in some cases be confused with a chancre: but the friable, irregular edges of the former, the liability to bleed, and the gradual progressive increase in size in spite of treatment in an elderly patient, should give rise to grave suspicion of malignant disease. Microscopical examination of a small piece removed from the edge of the ulcer will give direct evidence of epithelioma.

6. **Gummatous Ulceration** of the penis occurs occasionally, resulting from the disintegration of a small gumma of the glans or prepuce, frequently in the position of an old scar. A gumma commences as a small, elevated nodule, which, if left untreated, softens and discharges its contents, leaving an ulcer bounded by thin edges and with a yellowish, sloughy base. A gummatous ulcer has been mistaken for a primary lesion of syphilis: but the absence of induration, the history of the onset and of a previous infection with syphilis, would be points against a chancre. A second infection with syphilis is by no means unknown, especially in those who have had salvarsan alone in the treatment of the first attack, but it is rare. Occasionally the base of a gummatous ulcer proliferates into a papillary tumour and has given rise to a suspicion of carcinoma: the diagnosis will be confirmed by the behaviour of the lesion under potassium iodide, when a tertiary syphilitic affection will clear up rapidly.

7. **Tuberculous or Lupoid Ulceration** of the penis is rare, and is generally associated with advanced tuberculous infiltration elsewhere. Tuberculous ulcers are usually shallow, with thin overhanging edges, painful, and multiple. The infection has resulted from the rite of infantile circumcision by the Jewish method. The diagnosis is clinched by discovering tubercle bacilli in films made from the discharge.

R. H. Jocelyn Swan,

SORES, PERINEAL.—Ulceration may be present in the perineum as the result of :

- | | |
|--------------------------------------|-----------------|
| 1. Cutaneous inflammations or injury | 4. Syphilis |
| 2. Urethral fistulae or suppuration | 5. Epithelioma. |
| 3. Prostatic suppuration | |

1. Cutaneous Inflammation or Injury. An ulcer in the perineum may result from *direct injury* to the area, or from inflammatory *infection of the sebaceous or hair follicles* of the cutaneous covering. An ulcer from these causes may be placed at the centre or to one side of the perineum, is movable on the deeper parts, and shows no track into which a probe can be passed. In women, ulceration of the perineal area may be associated with *gonorrhœal* or *septic vaginal discharge*. It may also arise from severe scratching caused by the irritation of such skin infections as *linca cruris* or *pruritus ani*.

2. Urethral Suppurations or Fistulæ.—During the progress of an acute urethritis a glandular follicle frequently becomes infected. The suppurative process leading from this in the bulbous urethra may extend towards the perineum and open externally, leaving a small fistula which may or may not discharge urine during the act of micturition. In a similar manner urinary fistulæ may result from inflammatory processes behind a urethral stricture, and in an old-standing case it is not uncommon to find a urinary calculus in the dilated portion of the urethra behind the stricture. When the urethral suppuration is acute and an abscess bursts in the perineum, the diagnosis will be quite obvious, and the ordinary treatment for an abscess, in addition to that of the acute urethritis, will usually suffice to cure the condition.

If, however, the perineal wound discharges urine it will be found that this occurs as a rule only during the act of micturition, as there is no interference with the vesical sphincter. In nearly all cases, however, a stricture of the urethra will be found, though not necessarily one of sufficient degree to cause severe interference with micturition. Endoscopic examination will show the presence of a urethral stricture, whilst behind it can be seen frequently the sloughy granulations denoting the position of the urethral opening of the fistula. Occasionally urine drains from a perineal fistula continuously, and not only during the act of micturition. In these cases there is constant soaking of the perineal skin, and frequently excoriation. That urine should leak constantly from the fistula denotes interference with the vesical sphincter, either by dilatation behind a tight urethral stricture, by the presence of a calculus in the prostatic or membranous urethra, or by actual division of the vesical sphincter following some operation, such as perineal prostatectomy or perineal lithotomy.

3. Diseases of the Prostate.—An abscess or tuberculous focus in the prostate may occasionally discharge in the perineum, and remain as a sinus. An abscess in the prostate arises practically always from some infection in the posterior urethra, from venereal causes, or after septic instrumentation. It is accompanied by urethral discharge, or there is a history of a recent infection, whilst per rectum the prostate may be felt to be inflamed, and scarred from the shrinkage of the abscess cavity.

When a tuberculous cavity in the prostate opens in the perineum there is advanced tuberculous disease, so that little difficulty will be found in arriving at a diagnosis. A tuberculous prostate is very rarely a primary condition, but in most cases is secondary to disease in the testis or bladder, so that examination of these organs will in nearly all cases give evidence of tuberculous disease and indicate the nature of the perineal fistula. Palpation of the prostate per rectum may reveal the rounded nodular deposit of tubercle in the gland.

4. Syphilis may cause ulceration on the perineum either as a chancre or as mucous tubercles. A *chancre* at this site is rare. It forms a small ulcer with slightly indurated borders, indolent in character, and accompanied by slight enlargement of the inguinal lymphatic glands. A chancre of the skin does not possess the usual features of a genital chancre, and is not usually diagnosed with certainty until the secondary lesions of syphilis become apparent; but an ulcer with raised, infiltrated edges, which shows no tendency to heal under aseptic precautions, should always give rise to a suspicion of syphilis. The *Spirochæta pallida* may be looked for, and Wassermann's serum test tried.

Condylomata may be present about the perineum in association with active syphilis. They may extend from the anal or vulval orifice, and form oval or rounded, flat-topped,

sessile masses, covered by macerated, greyish epithelium, or they may be ulcerated on the surface. The accompanying signs of syphilis will indicate the diagnosis.

5. Epitheliomatous Ulceration of the perineum is practically seen only as a direct spread of a growth of the anus or vulval area, when the diagnosis presents no difficulty. An epithelioma may develop in the scar of some former cutaneous affection, in which case an ulceration may exist showing the usual characteristics of a cutaneous epithelioma, namely, gradual progressive increase in size, raised, friable edges, and tendency to slight hemorrhages. The inguinal glands may be enlarged early from inflammatory absorption, or later by infection with malignant disease. In case of doubt a fragment may be removed for microscopical examination.

SORES, SCROTAL. Ulceration of the scrotum occurs in association with :—

- | | | |
|---|---|--|
| 1. New growth :
Epithelioma
Papilloma | 4. Testicular disease :
Inflammatory
Tuberculous
Syphilitic
Carcinoma | Sarcoma
Embryoma |
| 2. Fistulæ | | 5. Suppurating cysts |
| 3. Syphilis | | 6. Irritants and corrosives,
such as mustard gas. |

1. New Growth. *Epithelioma of the scrotum*, commonly known as 'chimney-sweep's cancer', or 'tar-worker's cancer', is by no means limited to these avocations, but is certainly more common in men engaged in work in which they are exposed to much irritation from solid particles or from noxious fumes. Hence the disease is most commonly seen amongst chimney-sweeps, employes in gas-works, paraffin, tar, and chemical works, and coal-mines, and in mule-spinners in the cotton trade. It often begins as a small subcutaneous nodule, over which the skin is thinned and adherent : the nodule enlarges slowly, and the thinned covering gives way, to form an ulcer with thickened irregular edges and a tendency to bleed on slight injury. The ulcerated area extends both radially and into the tissues of the scrotum, later involving the testes. The inguinal lymphatic glands become enlarged soon after active ulceration commences, at first from inflammatory causes, later from malignant infiltration. In other cases a scrotal epithelioma begins in a *wart* or *papilloma*, which may have been present for years with only slight increase in growth. These soft papillomata are not unusually the starting-point of malignant change, when they become more vascular, whilst the surface epithelium becomes thinned and easily excoriated. A small amount of foul discharge is present, often encrusted into a scab, which on removal leaves an ulcer with indurated, everted edges, with the gradual progress of a cutaneous epithelioma. Any ulcer on the scrotum, especially if indurated or readily caused to bleed, must be looked upon with extreme suspicion, and when it does not improve with ordinary antiseptic medication, should be widely removed without waiting for glandular enlargement.

Epithelioma may occur in the scrotal area as a localized recurrence after removal of a malignant growth of the penis or testicle. Knowledge of the previous condition for which operation has been performed would give the diagnosis.

2. Fistulæ may occur in the scrotum and cause ulceration. They are most common in association with tuberculous or syphilitic disease of the testes, but occasionally they occur from urethral extravasation, or burrowing from rectal suppuration. An abscess may form and open through the scrotal skin from a peri-urethral abscess accompanying an acute urethritis or formed by septic infection behind a urethral stricture. In either case a small amount of urine may leak through the opening during micturition, whilst the history of urethral discharge, or of difficulty in micturition and other symptoms of stricture, will point to the diagnosis.

3. Syphilis of the Scrotum may be present either as a primary chancre or as a mucous tubercle. A *primary chancre* in this situation is by no means easy to recognize unless other signs of syphilis are present : but the presence of a cutaneous sore which does not show much inclination to heal under non-mercurial antiseptic dressings should always give a suspicion of syphilis. There is often only slight induration of the ulcer compared with that of a penile chancre, but the edge is raised and of a rolled appearance. The inguinal lymphatic glands are enlarged and discrete, and some five to six weeks after the commencement of the ulcer the usual secondary symptoms of syphilis become manifest.

Mucous tubercles may be present on the scrotum, usually on the femoral aspect. They may extend directly from the anal area. No difficulty will be met with in the diagnosis, as other signs of syphilis are obvious.

4. Testicular Disease. In some cases extension of disease in the testicle may involve the coverings of the scrotum, and may even perforate them to form a scrotal sore. This sequence occasionally occurs with : (1) A testicular abscess ; (2) Tuberculosis of the testis ; (3) Gumma of the testis ; (4) Carcinoma of the testis ; (5) Sarcoma of the testis ; (6) Embryoma of the testis.

A *testicular abscess* is somewhat uncommon, but may arise from direct extension from the urethra via the vesiculae seminales and vasa deferentia or by a haematogenous infection during the course of a specific fever, such as scarlet fever, mumps, or enterica. It may also follow chronic torsio testis. With urethral disease, the primary trouble may be due to gonorrhoea, or more frequently to a septic urethritis from the introduction of infected instruments, and is thus not infrequent in cases of prostatic enlargement in which the patient is passing his own catheter. In cases in which the infective process extends from the urethra the epididymis is affected first, whilst in the metastatic cases the body of the testis usually shows the first sign of enlargement. These acute inflammations of the testis occasionally suppurate, when the scrotal tunics become inflamed and adherent, whilst softening occurs later, and unless surgically relieved the abscess opens through the skin, leaving an ulcer, and a sinus discharging pus.

Tuberculosis of the testicle may occur as a primary disease or as a secondary deposit in association with tuberculosis elsewhere in the genito-urinary tract. Testicular tubercle almost always begins as a nodule in the epididymis, but in the later progress of the disease may extend into the testicle proper. If the tuberculous nodule progresses rather than undergoes cure, the scrotal skin becomes adherent, thinned, and finally perforated, leaving a shallow ulcer with thin, undermined edges, and discharging thin pus. Occasionally the necrotic tubules of the epididymis fungate through the opening in the scrotum, appearing as a greyish, sloughy projection from the cutaneous opening—the so-called ‘hernia testis.’

A *gumma of the testis* causes a swelling in the body of the testis rather than in the epididymis. A gumma which remains unrecognized or untreated may soften and ulcerate through the scrotal skin in a manner similar to tuberculous disease, leaving a clearly-defined ulcerated area with sharply-cut margins and a wash-leather-like sloughy base. The gummatous granulation tissue may fungate through the scrotal aperture, forming a yellowish necrotic mass.

The diagnosis of these three conditions may produce some difficulty in the earlier stages (see SWELLING, SCROTAL, p. 848), but in the advanced stage now under consideration, when an open scrotal sore is present, the diagnosis is easier. The *opening of a testicular abscess* on the scrotum leaves a small sinus discharging pus and accompanied by a general enlargement of the organ. Preceding the rupture of the abscess there is acute pain in the testicle, with rise of temperature, rigors, and general signs of suppuration, which are much diminished as soon as the abscess is allowed to burst. There is often a urethral discharge, which, however, is often much lessened with the onset of the acute epididymitis, with distinct thickening of the cord and aching pain in the neighbourhood of the external abdominal ring, or in metastatic cases the abscess occurs during the progress of an acute fever. The general history is one of acute pain commencing in the testicle, with rapid and extremely tender swelling of the organ, followed by abscess formation.

In *tuberculosis of the testis* the progress is much more gradual. A nodule may have been present in the epididymis for some time, gradually enlarging, but causing very little pain : in some cases a nodule may have been present for months without any apparent change, and then it may enlarge rapidly, involve the scrotal tunics, and discharge its contents. By the time the disease has reached this stage it is probable that evidence of tuberculous trouble will be found in other organs, particularly the other testis, prostate, seminal vesicles, or bladder. The affected testicle usually presents several nodules in the epididymis, tender on pressure, whilst small nodules may also be felt in the vas deferens.

The opening remaining from the discharge of a *gummatous orchitis* is usually a rounded ulcer with sharply-cut edges and yellowish base. The whole testis is enlarged, practically painless, and feels heavy. The cord is not thickened, and there is no evidence of disease

in the other testicle, prostate, or seminal vesicles. There is probably a history of syphilis, and other tertiary syphilitic lesions may be present elsewhere, such as gummatous periostitis. Strong evidence of the syphilitic nature of the disease is often obtained by the result of treatment with large doses of potassium iodide, alone or in combination with mercury or with salvarsan, when a gumma diminishes in size with marked rapidity. It should be remarked, however, that testes which are subsequently removed and found to contain large gummata may show no improvement before operation even under large doses of iodides, though the Wassermann test may be positive.

A *hernial protrusion of necrotic testicular tissue* may be present either with tuberculous disease or from a gumma. In tuberculosis the mass is greyish and necrotic, discharging thin pus, and there will be evidence of tuberculous disease in the underlying testis and other genital organs. Tubercle bacilli may be found in the discharge. A distinctive feature of the gummatous hernia testis is found in the appearance of the cutaneous opening: if the fungating mass be pushed aside the opening in the scrotal skin will be seen to be cleanly cut and to encircle the protruding tissue tightly. The fungating hernia testis of tubercle or syphilis must also be diagnosed from other conditions producing a raised tumour on the scrotum. An epithelioma of the scrotum has raised borders, but the centre is excavated, and there is rarely any enlargement of the testis. A sloughing papilloma of the scrotum may more nearly reproduce the appearance, but the tumour and the skin are freely movable on the underlying testis, whilst in hernia testis the mass is connected with the testicle, and the tubular structure of the latter is often apparent on picking up a small fragment of the fungating tumour.

New growths of the testis seldom cause ulceration of the scrotum because they have generally been removed by operation before so late a state is reached; any variety, however, whether carcinoma, sarcoma, or embryoma, may cause local recurrence in the scar, with ulceration: the diagnosis depends upon histological examination either of the tumour previously removed, or of snippings from the edge of the recurrence.

5. Cysts of the Scrotum. As an exceptional occurrence, a sebaceous cyst may develop in the scrotal skin, suppurate, and leave an open sore. The areas remaining present raised borders, and are easily mistaken for an early epithelioma. An accurate history of the previous swelling in the skin is of little assistance in these cases, but microscopical examination of a piece removed from the margin of the ulcer will exclude malignancy. A suppurating cyst in the scrotum is more uncommon than epithelioma.

6. Mustard gas caused most troublesome ulceration of the scrotum, as of other parts, during the war; but the diagnosis is easy if the correct history of exposure to this or some other irritant is available.

R. H. Jocelyn Swan.

SPASTICITY. (See GAIT, ABNORMALITIES OF, p. 313.)

SPEECH, ABNORMALITIES OF. Abnormalities of speech are numerous, varying from complete mutism to slight defects in articulation, and dependent on disturbances, functional or organic, in some part of the complex mechanism which is responsible for the production of intelligible language. This article is intended to expose the broad principles by which various abnormalities of speech can be detected and used for the purposes of diagnosis: it does not embrace a discussion of the controversial views which are held concerning their exact production.

The amount of investigation required for making a diagnosis in cases of speech abnormality varies within wide limits; great care is called for in examining cases of aphasia which result from disturbance in the function of the cerebral speech centres or their dependent paths of communication; the defective articulation of a patient suffering from cleft palate needs only a comparatively superficial examination in order to arrive at a correct diagnosis.

It will be convenient to consider the various abnormalities of speech under the following heads: (1) *Mental defects*; (2) *Aphasia*; (3) *Deaf-mutism*; (4) *Dysarthria*; (5) *Functional disorders—stammering, lalling, idioglossia*.

1. Mental Defects. The acquirement of the power of speech may be delayed in children who are mentally defective, and in some forms of idiocy may be suspended altogether. Before making a diagnosis of mental deficiency in a child who appears to be dilatory in

talking, it is well to remember that the age at which speech is acquired is very variable, and that the delay may be considerable where no mental impairment is present. In such cases the diagnosis must depend on a consideration of other points in the child's development. Inquiry should be made as to whether he is clean in his habits, whether he is destructive, whether he plays with toys or with other children in a natural manner, and whether he displays abnormally bad temper or irritability. In some cases the delay in speaking may be due to a defect in hearing which has been unsuspected by the parents. This point is especially apt to arise in respect to children who have begun to talk at the normal age, and who have lost what little they had learned of the art as the sequel of some acute illness.

In adults loss of speech may be due to many forms of mental deficiency of a temporary or permanent nature. A familiar example of temporary loss of speech is that degree of alcoholic intoxication to which the term 'speechless' is vulgarly applied. Similarly, the intoxication of the higher mental faculties associated with organic poisons, such as those of pneumonia or typhoid fever, may be responsible for temporary loss of speech. Complete mutism due to disease of the higher intellectual centres is common in various forms of dementia, and is proved to be no aphasic defect by the sudden and complete restoration of speech which may take place after months or even years of silence. The speechlessness of a melancholic patient or of one who is suffering from paralytic dementia is further differentiated from true aphasia by the fact that the latter is associated with attempts at communication, while the former is not. On the other hand, general paralysis of the insane is a disease in which temporary aphasia is by no means uncommon, especially in connection with the transient hemiplegia following 'congestive' attacks.

2. Aphasia. A definition of aphasia is difficult to supply in a few words. The term is used to denote that loss of speech which does not depend on mental deficiency, nor upon paralysis of the motor mechanism of articulation. Such a negative description requires, however, some modification, because aphasia is frequently associated with some impair-

ment of intelligence resulting from disturbance of internal language, which plays an important part in all intellectual processes, and any lesion of the cerebral centres connected with it must necessarily interfere with the higher mental activities. This is particularly the case in what is called sensory aphasia, that variety which depends upon a lesion of the auditory and visual word centres situated in the cortex near the posterior part of the left Sylvian fissure of the brain.

Fig. 602.—A diagrammatic representation of the left cerebral hemisphere, showing the chief centres concerned with speech.

In right-handed persons the chief speech centres are placed in the left cerebral hemisphere (Fig. 602), and it is customary to consider them as being three in number. The posterior part of the first temporal convolution is regarded as the area in which the auditory memories of spoken words are stored and recalled. It plays an important part in the development of speech, because it is largely through the sense of hearing that the child first learns to associate objects with their names and expressions with their meaning. The cortex in the angular gyrus has a similar special function in regard to the storage of visual word memories, a function which bears the same relationship to written language as the auditory word centre has to spoken language. These two portions of the cortex constitute the sensory speech centres. A third important centre is called the motor, or, better, the glosso-kinæsthetic centre, and this is located in Broca's area, or the posterior part of the third frontal convolution. In this situation are stored memories of afferent impulses excited by the motor activities employed in speech. Unless this centre is intact the conversion of internal into external language is imperfect or impossible. In the opinion of some authorities there is a similar cheiro-kinæsthetic centre in the posterior part of the left second frontal convolution, which plays a part in connection with written language comparable to the part played by Broca's area in relation to spoken language.

With these physiological and anatomical data as a basis, we can proceed to consider the chief varieties of aphasia and the points in their differential diagnosis. Before doing so, it is well to sound a note of warning with regard to the complications which are constantly being met with by the clinician in attempting to analyse cases of aphasia. In the first place, a diagrammatic anatomical definition of the cerebral centres is liable to give a wrong impression. These centres are more diffuse in their function than they appear to be on a map of the brain, and they are much more interdependent than their topography would suggest. Communicating nervous tracts bind them together in such a way that a destructive lesion of one must necessarily upset the function of another, and so modify the clinical picture of any particular case profoundly. Aphasia is, in most instances, the result of a vascular lesion, and all the centres referred to lie in the area supplied by one artery—the middle cerebral. Consequently even when the main brunt of a vascular disturbance falls on one of the special speech centres, the others may also suffer more or less, temporarily or permanently, from disturbances of nutrition. In any case of aphasia, therefore, we may have to be satisfied if we can arrive at a conclusion as to the site of the chief defect, without being able to define the exact limits of the loss or impairment of cerebral function. Again, due allowance must be made for the fact that the right cerebral hemisphere may gradually acquire some degree of speech activity, especially in cases of aphasia occurring during the earlier years of life, and may tend to replace the loss caused by the defective action of the left.

Word-deafness is the result either of a lesion of the auditory word centre in the temporal cortex, or of one which isolates that centre from the periphery—that is to say, of a sub-cortical lesion cutting off the centre from auditory impulses. In either case the patient who is word-deaf is unable to recognize the meaning of spoken language, although he may hear perfectly the sounds by which it is conveyed. He fails to understand anything which is said to him, and does not obey simple commands so long as they are not accompanied by gestures suggestive of their meaning. If the visual word centre has not been affected at the same time, he will still be able to read and to understand what is written. He will depend upon writing and reading for his means of communication with others. The amount of interference with spontaneous speech will depend upon whether the lesion is cortical or sub-cortical. If the latter the integrity of the auditory word centre preserves internal speech, and so permits the patient to speak spontaneously with fluency and probably with accuracy, and his power of writing will be equally unimpaired. When the cortical centre is itself destroyed, internal language is thoroughly disorganized, and although some spontaneous speech may be possible, it is certain to be more or less unintelligible. According to the extent of the lesion it will vary between a speech containing inaccuracies of minor importance and one which is a jargon incapable of interpretation. Characteristic of this defect is the fact that the patient himself does not appreciate the mistakes he makes. His written language is likely to be more accurate and more intelligible than his spoken language, but it will probably not reach a very high standard. He may copy with accuracy, but be quite unable to write from dictation. Such are the usual chief attributes of word-deafness in its pure form. Clinically, word-deafness is usually accompanied by word-blindness, to a greater or less extent.

Word-blindness, or *Alexia*, is produced by a lesion of the left angular gyrus, and may or may not be accompanied by a defect in the field of vision. As in the case of word-deafness, it may result from a cortical or from a sub-cortical lesion, and it is in association with the latter class of case that *HEMIANOPSIA* (p. 377) is most common. In cortical word-blindness the patient is unable to read, although he sees the letters clearly and may even be able to copy them in the same way as a child copies letters when learning the alphabet. Writing conveys no meaning to his mind, although in the less severe cases the patient may still recognize familiar words, such as his name. There are, in fact, varying degrees of word-blindness, some of which are difficult to understand and to analyse. The word-blind patient suffers in his spontaneous speech to a greater or less extent according to whether he uses his visual or his auditory memories chiefly in the process of internal language. Should he be a 'visual' his spontaneous speech will suffer much more than if he is an 'auditive'. The terms 'visual' and 'auditive' are used to distinguish two classes of persons, the first depending more on their visual memories of words and the second more on their auditory memories of words in the course of reviving them for the purposes of

internal thought and speech. Spontaneous writing is likely to be lost completely, but writing from dictation may be carried out with more or less accuracy. In word-blindness due to a sub-cortical lesion, although hemianopsia is almost certain to be present, spontaneous speech and spontaneous writing are preserved perfectly, although the power of reading and of copying hand-written sentences into printed capitals is entirely in abeyance.

When word-blindness and word-deafness co-exist the condition is called *sensory aphasia*, and is one to which some authorities believe that the term aphasia should be limited. It is, however, usual to describe a motor aphasia which may be dependent upon a cortical or sub-cortical lesion.

Cortical motor aphasia results from a destructive lesion of Broca's area, the part of the cortex which stores memories of the afferent impulses excited by speech, and in which such memories must be revived if spontaneous speech is to be carried out perfectly. This form of motor aphasia may be present without any paralysis, but it is usually accompanied by some disturbances of internal speech, and perhaps even by some defective understanding of spoken and written language, which, however, never amounts to true sensory aphasia.

Much more common is the *sub-cortical motor aphasia*, which is due to a lesion cutting off Broca's cortical area from the motor mechanism connected with articulation. In this form intellectual processes and internal language may be perfectly intact, but in most cases the inability to speak is associated with right hemiplegia in right-handed persons, or with left hemiplegia in left-handed individuals. The imperfect speech of the patient who is partly aphasic from a sub-cortical motor lesion may resemble to some extent that of the patient who is word-deaf: but the former is conscious of his mistakes and the latter is not. Sub-cortical motor aphasia may perhaps be described better as an articulatory rather than a speech defect: as an *anarthria* rather than an aphasia. All the attributes for speech are preserved, but its emission is impossible.

Agraphia results usually from a lesion of the visual word-centre, or perhaps in some cases from a lesion of the posterior part of the left second frontal convolution. In the former case the power of writing may be lost, although there is no paralysis of the arm or hand. In the latter case the agraphia is usually associated with right hemiplegia, and in order to test whether the power of communicating thoughts by written language is preserved, the patient must be asked to use the left hand for the purpose. There is some doubt as to whether pure motor agraphia occurs, and some doubt as to the lesion upon which it may depend. I have had experience of the clinical occurrence of pure motor agraphia without being able to correlate the phenomenon with its anatomical basis.

We have now considered the various forms of aphasia and have indicated their points of distinction. This will serve as a basis for diagnosing the site of the lesion responsible for the speech defect, but the nature of the lesion must be determined from other considerations. Vascular lesions, for instance, are usually acute in their onset, sudden in the case of *embolism*, less precipitate as a rule in cases of *hemorrhage* or *thrombosis*. With *cerebral tumour* or *abscess* the onset of symptoms is more gradual, and local troubles such as that of *hemianopsia* are generally accompanied or preceded by the symptoms of increased intracranial pressure in the form of headache, vomiting, and optic neuritis. But aphasia is not always the result of a gross and permanent lesion. Transitory aphasia may be observed in the sequel of epileptiform convulsions, or may be in itself an *epileptic equivalent*—a form of *petit mal* in an epileptic subject. Temporary aphasia occurs also in connection with *migraine*, and I have known it to occur at intervals during a period of thirty years in a woman who was perfectly healthy in every respect, and who showed no other symptoms suggestive of either epilepsy or migraine.

3. **Deaf-mutism.**—The diagnosis depends upon the events observed as the child grows up: the condition is either congenital, or the effect of ear disease and deafness acquired in infancy.

4. **Dysarthria**, or in its extreme form *'anarthria'*, is the term used to describe defective articulation as opposed to defective speech. Articulation is carried on by certain muscles of the larynx, pharynx, palate, tongue, and lips which are innervated by the bulbar nuclei, and the latter are set into action by voluntary impulses coming from the motor cortex of both cerebral hemispheres via the pyramidal tracts. The articulatory movements, therefore, are represented bilaterally in the brain, and, like other bilaterally represented movements of the body, are not disorganized by unilateral lesions of the pyramidal system.

Thus, in cases of hemiplegia without aphasia, there is little or no defect in articulation, and the examination of such a patient shows that both vocal cords, both sides of the palate, and the tongue, retain their power of voluntary movement almost, if not quite, to perfection.

Suprabulbar dysarthria is induced, however, in cases of *double hemiplegia* when the fibres from both hemispheres to the bulbar nuclei are interfered with by destructive lesions. When a right-sided stroke is followed by a left-sided stroke, or when double hemiplegia results from a lesion in the pons, dysarthria results. In such cases the power of speech may be perfect, but the ability to articulate naturally and clearly is disturbed. The patient is not aphasic but dysarthric. Articulation is usually slow, spastic, and indistinct, if it is not altogether unintelligible. These cases are differentiated from cases of dysarthria due to lesions of the bulbar nuclei or of the cranial nerves, not only by the presence of other hemiplegic signs in the limbs and trunk, but by the fact that the tongue retains its shape, nutrition, and normal electrical reactions, and the palate its natural reflex. This condition of *pseudo-bulbar palsy*, as it is sometimes called, is further distinguished by facial starchiness or spasticity, and by the patient's inability to control the expression of his emotions.

Dysarthria of similar origin, but generally of less degree, may be observed in cases of *general paralysis of the insane*, in *cerebral diplegia*, and in *disseminated sclerosis*. In the latter disease the term 'staccato' or 'scanning' is applied to describe the articulatory defect. Some cases of *Friedreich's ataxy* exhibit a form of articulation which is slow and jerky, not unlike that of disseminated sclerosis. Probably some degree of inco-ordination enters into the production of this peculiar utterance. In all these diseases the diagnosis of the condition depends upon the presence of other symptoms and physical signs, and can rarely be deduced from the articulation alone.

Dysarthria also arises from disease of the bulbar nuclei, or of the nerves arising from the latter which supply the muscles of the larynx, pharynx, tongue, and lips. In true *bulbar palsy*, which is a disease depending on a slowly progressive degeneration of these motor nuclei, articulatory defects are often among the earliest symptoms. The diagnosis of these cases is based on the fact that the symptoms begin insidiously and progress gradually, that the paresis affects the muscles of both sides more or less symmetrically, and that it is an atrophic form of paralysis. The atrophy is seen best in the tongue muscles, and is usually associated with a certain amount of fibrillation, and with diminution of their electrical excitability. The palatal reflex is also impaired, and examination of the vocal cords shows that they too are the seat of a progressive palsy. The dysarthria is always accompanied, sooner or later, by some degree of dysphagia, and also by some weakness and atrophy of the muscles of mastication. Atrophic palsy may also be observed in the small muscles of the hands, and there is a tendency to exaggeration of all the tendon reflexes in the limbs. A similar clinical picture may develop in cases of gross disease of the bulb, due either to local softening or hæmorrhage, or in rarer cases to the gradual growth of a tumour in that region. Such cases can be differentiated from true bulbar palsy, partly by the more acute onset of symptoms in the case of the *vascular lesions*, and partly by the asymmetrical distribution of the muscular atrophy and paresis when a *tumour* forms the basis of the disease. *Gummatous meningitis* at the base of the brain may involve the cranial nerves close to their exit from the bulb, and so produce a dysarthria of a somewhat similar character. When tumour or meningitis is the cause of dysarthria, symptoms of increased intracranial pressure are likely to be observed.

Another form of bulbar palsy is seen in cases of *myasthenia gravis*. In this condition there is little or no atrophy of the articulatory muscles, although some thinning of the tongue is observed sometimes. The distinguishing characteristics of this dysarthria are first of all its marked variability, and secondly the effect produced by fatigue. A myasthenic patient may begin a conversation, or may begin to read aloud from a book, without showing much difficulty in his utterance, but, as he progresses, his articulation becomes more and more defective and more difficult to understand. Usually the palate fails quickly, and a nasal quality is given to the voice. If he is asked to repeat the word 'rub' many times, the terminal 'b' becomes an 'm', and he ends by saying 'rum' instead of 'rub'. Most cases of myasthenia gravis exhibit similar fatigue phenomena in relation to other parts of the musculature (see *Fig. 245*, p. 291), and in particular showing varying degrees of

ocular palsy, which, like the dysarthria, is at one time more marked than at another, and is much influenced by rest and exercise.

Some articulatory defect is produced by bilateral peripheral palsy of the palate, which most often results from the effects of the *diphtheria poison*. The voice is nasal, and the pronunciation of certain consonants becomes impossible. 'B' becomes 'm', 'd' becomes 'n', and 'k' sounds like 'ng'.

Bilateral facial palsy interferes with that part of articulation which depends upon the labial muscles, and so renders speech indistinct, although not unintelligible. Facial palsy of this kind (*Fig. 464*, p. 603) is met with in some cases of peripheral neuritis and also in some cases of myopathy, especially that form to which the name Landouzy-Dejerine is applied.

Unilateral bulbar palsy may exist without much interference with articulation or phonation. There may be considerable palsy of one vocal cord due to a lesion of one recurrent laryngeal nerve, without a recognizable alteration in the character of the voice. A bilateral laryngeal palsy, when complete, leads to aphonia. Similarly, unilateral palsy of the palate or of one half of the tongue may exist without articulatory defect, especially after the patient has become accustomed to the altered conditions.

5. Functional Disorders of Speech.—In cases of hysteria a *functional aphonia* is by no means uncommon, and in many cases can be distinguished from aphonia due to organic disease only by an examination of the larynx. Hysterical aphonia may be complete; in other cases the voice is reduced to a whisper, and yet the patient is able to adduct the cords properly in coughing. This is sometimes a recurrent malady, and the suddenness of its onset, as well as the suddenness with which it is often cured, are characteristic.

Stammering is another type of functional dysarthria, and presents a large variety of forms. There is little difficulty in their recognition, because in all cases when once the articulatory flow is established the utterance is perfectly normal. The difficulty generally arises either in commencing a word or a sentence, or in connection with certain consonants. Some of the cases depend on an initial spasm of the articulatory muscles, and others upon an inco-ordination between the action of the respiratory muscles, especially the diaphragm, and those which have to do with phonation and articulation. The complete absence of physical signs of disease, and the history of the case, make the diagnosis easy. On the other hand, stammering is occasionally an early symptom of progressive degenerative conditions of the central nervous system, especially of general paralysis of the insane.

The term '*lalling*' is applied to a defective form of articulation met with chiefly in persons who are more or less mentally feeble. It is characterized by what appears to be an imperfect pronunciation of certain consonants. In more severe cases one consonant is consistently replaced by another, such as 'r' by 'w'. These mistakes in pronunciation are common enough in normal children when learning to speak, but the endurance of the defect after the learning age is passed generally indicates some permanent mental deficiency. A temporary perversion of speech is seen occasionally in children before they learn the proper use of language. They may talk glibly and fluently in a language which they appear to understand themselves but which is unintelligible to their neighbours. In this condition, to which the term '*idioglossia*' is generally given, the prognosis may be regarded as favourable.

SPINAL CURVATURE. (See CURVATURE, SPINAL, p. 191.)

SPLEEN, ENLARGEMENT OF THE.

The Physical Signs of Enlargement of the Spleen.—If the organ is enlarged only slightly or moderately there is no alteration in the size or shape of the abdomen; if it is enlarged considerably or enormously the abdomen may be much distended, and at a first glance this distention may appear to be uniform, as though due to ascites. Closer inspection may show that it is by no means uniform, there being distinct bulging of the left side, especially in the left hypochondrium, the left lumbar, and the left half of the umbilical regions. The inner border of the spleen may be tilted forward in some cases so that a distinct edge or ridge may be seen pushing the abdominal wall forward, this ridge running downwards and inwards from the left costal margin near the anterior axillary line towards the umbilicus; in a few cases a distinct notch can be seen in this edge or ridge. When

the patient takes a deep breath, the prominence may be seen to move distinctly downwards, though occasionally the spleen may be so enormously enlarged that its lower end becomes impacted in the pelvis, when no downward movement is possible.

Palpation is the best means of detecting splenic enlargement. If the organ is but little enlarged it may not be felt until the observer, standing upon the left-hand side of the recumbent patient, and supporting the lower left ribs posteriorly with his right hand, steadily but firmly presses the fingers of his left hand under the left costal margin just in front of the anterior axillary line : when the patient now takes a deep breath, a definite sense of increased resistance may reveal splenic enlargement when the organ is comparatively soft, as in many cases of typhoid fever for example, or a hard mass with a distinct edge may be felt in more obvious cases. When the enlargement is moderate or considerable, the splenic tumour will be felt coming down from beneath the left ribs close behind the abdominal wall : and unless there is a very large liver at the same time, or some other cause preventing the viscus from following its natural direction as it enlarges, it tends to reach and ultimately cross the middle line at or just below the level of the umbilicus. It is generally smooth and firm, and the characteristic notch or notches can be felt in its anterior border. Except in those rare cases in which the whole spleen is dislocated it will not be possible to insert a hand between it and the left costal margin, or define its upper limit by palpation. The lower pole can be felt to move decidedly downwards on inspiration, unless the enlargement is very great. On bimanual palpation, the loin is not filled out as it would be by a renal tumour, and the mass cannot be pushed back into the loin so as to be felt by the posterior hand as readily as it is by the hand on the anterior abdominal wall.

Percussion yields a dull note over the mass, the dullness being directly continuous with an increased area of dullness in the thorax extending upwards as high as the seventh rib in the mid-axillary line, the sixth rib in the nipple line, or even higher, and including the ordinary area of splenic impairment of resonance behind. Percussion of the left loin may elicit resonance here, indicating that the colon is not displaced as it would have been by a renal tumour : no intestines can be felt or percussed over the front of the spleen. It is sometimes possible to demarcate the spleen by percussion when the patient is lying at full length but with the body turned half over to the right so that the right flank is on the bed and the left flank is uppermost : if he then raises his left arm so as to take hold of the top bed-rail with his left hand, the observer percusses the 10th rib, from its vertebral end forwards, when it is often possible to determine, by the change of note, where the upper pole of the spleen begins : and again, by the change of note further along the 10th rib, the situation of the lower splenic pole.

Auscultation seldom affords much evidence of value in these cases, but sometimes when the splenic enlargement is associated with local peritonitis, as in cases of infarction for example, a loud rub may be heard over the mass when the patient takes a particularly deep breath : sometimes, especially if the enlargement is associated with venous engorgement, a well-marked continuous humming bruit may be heard.

Distinction between an Enlarged Spleen and other Tumours which may simulate it. An enlarged spleen has to be distinguished from other tumours which may arise in the left hypochondriac region, especially from : (1) Kidney tumours or perinephric inflammation or abscess ; (2) Suprarenal tumours ; (3) Carcinoma of the splenic flexure of the colon : (4) Pancreatic tumours, especially cyst or carcinoma ; (5) Malignant growth of the stomach ; (6) Ovarian tumour ; (7) Tuberculous peritonitis ; (8) Faecal accumulation in the colon.

Distinction from a Renal Tumour.—It may be difficult to distinguish an enlarged spleen from a kidney in some cases. Both conditions may cause local prominence or bulging of the left side of the abdomen : in the case of splenic enlargement the bulging is more forward and inward, whereas in a kidney enlargement the loin is more likely to be bulged. No distinct edge or notch can be seen or felt in the case of most renal enlargements. Either tumour may move downwards when the patient takes a deep breath : but the spleen, being in closer contact with the under surface of the diaphragm, moves the more markedly of the two. A renal tumour being situated more deeply in the abdomen seldom approximates closely to the anterior abdominal wall unless the enlargement is very great, in which case the loin will be filled out and feel very firm and resistant on bimanual examination.

A renal tumour generally slopes away as it approaches the ribs, so that it is less difficult to get one's hand between its upper pole and the costal margin than is the case with the undislocated spleen. The colon may be seen or felt over the anterior surface of a renal tumour, which is never the case with splenic enlargement; and percussion may yield a resonant note in front, or in typical cases a vertical band of colonic resonance down the centre of an otherwise dull mass, the loin posteriorly being dull; whereas with a splenic tumour the loin may be resonant, and the anterior aspect of the mass quite dull. The presence of a local bruit or rub would make renal tumour unlikely. The occurrence of HÆMATURIA (p. 347), PYURIA (p. 715), or ALBUMINURIA (p. 4) would suggest renal enlargement, whilst the condition of the blood might be such as to suggest splenic.

Notwithstanding all these points, to distinguish between splenic and renal masses is sometimes by no means easy; and it is only by paying careful attention to the history and the patient's own sensations, as well as to the physical signs and the changes in the blood and urine, that a correct diagnosis can be made.

Malignant Disease of the Left Suprarenal Gland may cause a large mass which is sometimes difficult to distinguish either from a splenic or from a renal enlargement. Owing to the close proximity of the suprarenal capsule to the kidney, and the liability for the capsule of the latter to become infiltrated by growth of the former, the physical signs of a suprarenal are practically the same as those of a renal tumour, except that it may be more difficult to pass the hand between the mass and the costal margin. Hæmaturia and other urinary changes may result from spread of the disease to the kidney; affection of one suprarenal gland alone does not produce Addison's disease, and it may be impossible to arrive at a correct diagnosis without laparotomy. A peculiar affection of children deserves special mention: at a comparatively early age there may be an abnormal development of the pubic and axillary hair and of the genital organs (see *Figs.* 394, 395, p. 508), with premature puberty, associated with overgrowth of suprarenal rests in the kidney, the resultant tumour being spoken of as a *hypernephroma*.

Carcinoma of the Splenic Flexure of the colon is usually annular, giving rise to no definite tumour, but rather to symptoms of chronic, followed by acute, intestinal obstruction. Occasionally, however, the growth may be more voluminous, or it may have caused leakage and inflammatory matting from local perforation through or above the growth, with the result that a fairly large tumour may be felt in and below the left hypochondrium. This mass is generally resonant to percussion, has no well-defined edge or notch, and may vary somewhat in position from day to day: it will usually be associated with intestinal symptoms, especially constipation alternating with diarrhœa, and the passage of mucus, and occasionally blood, per rectum. Sometimes there are obvious secondary deposits in the liver or the left supraclavicular glands. In case of doubt it will be necessary to get radiograms of the colon after a bismuth meal, or alternatively after a bismuth enema (*Fig.* 143, p. 163).

Pancreatic Tumours are usually situated more in the median line of the abdomen than a spleen, between the ensiform cartilage and the umbilicus; sometimes, however, a very large cyst, such as may nearly fill the abdominal cavity, may cause considerable difficulty in the diagnosis. One very important point is that no definite edge and no notch can be felt. The stomach generally lies in front of a pancreatic cyst; or, if the latter pushes its way forward so as to displace the stomach upwards and the transverse colon downwards, it may be possible to define its relationship to the stomach by inflating the latter with gas, by giving a Seidlitz powder without mixing the two halves of the latter beforehand. A splenic tumour rarely extends to the right of the middle line unless the enlargement is great, and then it crosses at or below the umbilicus, whereas a pancreatic cyst reaches across to the right of the middle line above the navel. Pancreatic new growth has a similar position; but the outline of the mass, if any can be felt at all, is more nodular; there will generally be jaundice and a palpable gall-bladder, and the urine may yield CAMMIDGE'S PANCREATIC REACTION (p. 128).

Malignant Growth of the Stomach may be mistaken for enlargement of the spleen, especially gastric sarcoma, which, though very much rarer than carcinoma, is more likely to involve the whole of the stomach and give rise to a very large tumour occupying chiefly the upper part of the left side of the abdomen. The following changes will serve to distinguish a gastric new growth from enlargement of the spleen: the mass is apt to shift its position slightly during the course of an examination or from day to day; it does not

present a well-defined edge with definite notch or notches : it may extend a considerable distance to the right of the middle line, although its lower limit may not be below the level of the umbilicus : it is likely to be resonant in front, though the percussion note over it may be impaired : there may be anaemia and leucocytosis, but the blood-changes would not be characteristic of any positive blood disease : the taking of food may cause an increase in the gastric pain : vomiting will generally be a prominent symptom : the vomit may contain blood, obvious or occult : free hydrochloric acid may be deficient or absent : *sarcinae ventriculi* may be found (*Fig.* 258, p. 302) : and there may be secondary deposits, especially in the liver or in the left supraclavicular glands. Examination of the stomach with the X rays after a bismuth or barium meal may also assist or clinch the diagnosis (*Figs.* 277-280, pp. 340, 341).

Ovarian Tumours have been mistaken for enlargement of the spleen, and vice versa, the differential diagnosis being particularly difficult in cases in which the spleen has become dislocated, or is so large as to reach down as far as the uterus. The organ has sometimes been found so dislocated as to lie wholly within the pelvis. The differential diagnosis depends in most cases on the following points : an ovarian tumour rarely extends upwards to such an extent that its upper limit comes into actual contact with the left costal margin so that the hand cannot be placed between it and the ribs : it does not move much downwards during deep inspiration : it extends upwards from the pelvis, whence it may be felt definitely to arise, the lower part of the abdomen being more prominent than the upper : it is usually more globular than a splenic tumour, and has no sharp, well-defined edge with notches in it, even when covered with projecting bosses of simple or malignant new growth : it usually extends more to the right of the middle line than an enlarged spleen does : and it is more apt to transmit aortic pulsations : a vaginal examination may determine that the mass is attached to one or other of the broad ligaments, and that the cervix and the body of the uterus are drawn upwards : there will probably be no distinctive blood-changes, but very likely amenorrhœa.

Tuberculous Peritonitis may cause various abdominal tumours (see p. 64), and sometimes gives rise to a mass occupying the left hypochondriac region, the result of matting together of the intestines, thickening of the omentum, or thickening and infiltration of the peritoneum attached to the abdominal wall here. The tumour does not generally extend close up under the ribs, so that the hand may be placed between it and the costal margin, and although it may feel somewhat rounded, with a more or less well-defined edge, there is no definite notch to be felt : sometimes, however, when there are two, three, or more separate masses united together a notch may be simulated to some extent. The mass itself may be dull, but there is generally resonance between it and the normal splenic dullness. Ascites is often present, and there may be palpable lumps in other parts of the abdomen, or perhaps redness and œdema of the abdominal wall, or a purulent or faecal discharge from the umbilicus. Indeed, tuberculous peritonitis is the commonest cause of acquired umbilical fistula, the next commonest cause of the latter being pneumococcal peritonitis which has recovered slowly, either without or with operation. There may be signs of tuberculosis elsewhere, for instance in joints, or lymphatic glands. Calmette's or von Pirquet's tuberculin reactions may be positive. The patient will generally be young, and have consumed unsterilized cow's milk. Pyrexia may be present or absent, either with tuberculous peritonitis or with splenic affections, so that its occurrence does not assist the diagnosis much, except perhaps that if the chart exhibits marked evening pyrexia in a young subject, with a subnormal temperature in the morning, it is an additional argument in favour of tubercle. The reverse type of pyrexia—morning rise and evening fall—has been spoken of as characteristic of tubercle, but it is seldom met with.

Fæcal Accumulation in the Splenic Flexure or adjacent parts of the transverse or descending colon may be mistaken for an enlarged spleen upon a first examination : but this source of error is usually removed when the patient is re-examined after an action of the bowels has taken place. The condition is found most frequently in women if the age is not great, or in elderly people of either sex. There is generally a history of severe obstipation, and possibly attacks of temporary obstruction. The mass is generally irregular, more or less cylindrical, and in thin persons it may be possible actually to alter its shape by manipulation with the hand. The best test of the condition, however, is the effect of copious enemata upon the mass.

Hæmatoma due to Leakage from an Abdominal Aneurysm is a rarity, but it may be mistaken for an enlargement either of the spleen or of the kidney, unless the aneurysm itself can be felt pulsating; or unless there is a history or an acute exacerbation of intra-abdominal pain, accompanied by blanching due to the amount of blood lost.

CAUSES OF SPLENIC ENLARGEMENT.

Having concluded that the spleen is enlarged, the next step is to decide the cause of the enlargement. There are various ways in which the different causes may be classified, but from a diagnostic point of view the following is serviceable:

1. Chronic Enlargement of the Spleen.—

1. *Very great enlargement* :—

Splenomedullary leukaemia	Splenomegalic polycythæmia	Gaucher's disease
Lymphatic leukaemia	Splenomegalic cirrhosis	Still's disease
Mixed leukaemia	Splenic anaemia	Familial acholuric jaundice
Chronic malaria	Pseudo-leukaemia infantum	Egyptian splenomegaly.
Kala-azar		

2. *Moderate enlargement*.—All conditions mentioned in Group 1 will at some stage exhibit a spleen that has not yet become enormous; and besides these, chronic and moderate enlargement of the spleen may be exhibited in cases of:

Pernicious anaemia	Lardaceous disease
Rickets	Thrombosis of the portal vein
Congenital syphilis	Pressure on the portal vein by enlarged lymphatic glands or by adjacent tumour of the gall-bladder, liver, pancreas, stomach, etc.
Hodgkin's disease	
Cirrhosis of the liver	

II. Acute Enlargement of the Spleen, the Enlargement as a rule being Slight.—

1. *Acute infective fevers* :—

Especially—

Typhoid fever	Typhus fever	Malta fever	Septicæmia
Paratyphoid fever	Malaria	Erysipelas	Trench fever.
Relapsing fever			

Less often in—

Pneumonia	Scarlet fever	Rheumatic fever	General tuberculosis.
Diphtheria	Small-pox	Influenza	

2. *Embolism*, especially in cases of fungating endocarditis.

3. *Injury or Strangulation* by twisting of the pedicle.

It will be noted that no mention is made of abscess, gumma, carcinoma (whether primary or secondary), sarcoma (primary or secondary), or hydatid cyst of the spleen, for these are all so exceedingly rare they are very unlikely to be met with. It will also be noted that no mention is made of backward pressure, whether due to chronic valvular disease of the heart with failing compensation, or to obstruction to the inferior vena cava above the hepatic veins, such as may result from thrombosis or from pressure upon the veins by mediastinal fibrosis or new growth: these conditions are omitted purposely, for it is quite exceptional for ordinary backward pressure to produce enlargement of the spleen. So true is this that in a case of chronic valvular heart disease with failing compensation the existence of a definitely palpable spleen is evidence of there being more than mere mechanical heart-failure—probably superposed fungating endocarditis. The chief exceptions to this occur in childhood, where the spleen becomes palpable more easily than in adults, so that with heart-failure in a child enlargement of the spleen is less good evidence of fungating endocarditis than it is in a grown-up person.

I. CHRONIC ENLARGEMENT OF THE SPLEEN.

1. **Chronic and very great Enlargement of the Spleen.**—When the spleen is so large as to occupy half the abdomen or more, the diagnosis is generally easy. The largest of all spleens are those due to *splenomedullary leukaemia*. The first step is to make a full examination of the blood, including particularly total and differential leucocyte counts. If there

is an extreme degree of leucocytosis, up to anything between 50,000 and 1,500,000 per c.mm. for example, the diagnosis is almost certainly leukaemia, and if in the differential leucocyte count there are from 20 to 50 per cent of myelocytes, it is of the splenomedullary type, whilst if the lymphocytes amount to 90 per cent or more, the disease is of the *lymphatic* form, in which the lymphatic glands are almost certain to be enlarged as well

as the spleen: in some cases of lymphatic leukaemia the latter may be scarcely enlarged at all, but in others it may be almost if not quite as large as in the splenomedullary type of the disease. For mixed leukaemia, see ANÆMIA (p. 35). In the absence of any marked leucocytosis, or of characteristic differential leucocyte counts (see also ANÆMIA), the diagnosis of the nature of a very large spleen will depend in the first place upon whether there has or has not been residence in a malarial region—the fen districts of Great Britain, the tropics, or certain parts of Europe, particularly Italy. The *ague-cake* spleen of the

fens is now very rare : it is more often found in chronic cases of tropical malaria, when the history may indicate its nature, and if the patient is having febrile attacks, the parasites (*Figs. 57-60*, pp. 40, 41) may be found in the blood. Recent investigations have shown that some, at least, of the enlarged spleens formerly attributed to malaria are due to other infections. One of these has been differentiated clearly from the rest, namely *kala-azar*, which occurs in India, particularly in Assam, in Africa, and in Sicily, and is diagnosed chiefly by the discovery of the Leishman-Donovan bodies in the fluid obtained by splenic puncture (*Fig. 605*).

Splenomegalic Polycythæmia, Erythræmia, Osler's Disease, or Vaquez's Disease is a rare affection of adults, characterized by more or less cyanosis (*Fig. 515*, p. 652) and symptoms which might suggest a cardiac lesion, together with more or less enlargement of the spleen, and polycythæmia amounting perhaps to six, seven, ten, or even twelve million red corpuscles per c.mm. In most cases the spleen, though definitely enlarged, broad, and firm, comes only a few finger-breadths below the ribs; enormous enlargement of the spleen is unusual here. The malady is generally chronic, extending over years, with an insidious onset and slow progress. The first symptoms are vague, with progressive loss of working power, and some shortness of breath on exertion. Hemorrhages may occur early, or at any stage of the malady : especially bleeding from the mouth, epistaxis, hamoptysis, hamatemesis, hamaturia, or melæna. Purpura is not common. The patient's heart is generally hypertrophied and dilated to some extent, with or without a systolic apical bruit : and the blood-pressure is above the normal : it may be anything between 150 and 250 mm. Hg. The patient does not usually waste. He may develop effusion into any of the serous cavities. The diagnosis is arrived at when polycythæmia and enlargement of the spleen occur in the absence of any definite cause.

Splenomegalic Cirrhosis is an affection of children and young adults, in whom there are likely to be more or less jaundice, anæmia, lack of development, and ultimately ascites, as well as considerable enlargement of the spleen. There is a tendency for this malady to affect more than one member of a family, and this sometimes gives the clue to the diagnosis : though it may often be a matter of mere personal opinion as to whether the label should be splenomegalic cirrhosis or familial acholuric jaundice (pp. 445, 781), so ill-defined are the points of distinction between one group and another of these juvenile big-spleen patients. If there are bile pigments in the urine and if there is no undue fragility of the red cells, acholuric jaundice will be the less likely, and vice versa : but it is often very difficult indeed to label some cases : for instance, when there is undue fragility of the red cells together with bile pigments in the urine, or when, though the patient is jaundiced yet presents no bile pigments in the urine, there is no undue fragility of the red cells. When death ultimately ensues in cases that can be labelled splenomegalic cirrhosis definitely, one finds in association with the great big spleen a hard fibrotic or cirrhotic liver, and sometimes the liver is indistinguishable from that of ordinary alcoholic cirrhosis. What relationship this malady has to ordinary alcoholic cirrhosis of the liver on the one

and, and to splenic anæmia or Banti's disease upon the other, is not clear : but owing to the enlargement of the spleen, it is differentiated as splenomegalic cirrhosis. Hemorrhages, particularly hamatemesis, are not infrequent in this as in other forms of cirrhosis of the liver. The blood-changes are merely those of a simple chlorotic anæmia. The diagnosis is afforded chiefly by the age of the patient, by the size of the spleen, and by the absence of any positive blood-changes, particularly if more than one member of the family is affected in the same way. The patient often lives for a number of years, and is able to work in spite of the complaint until ascites supervenes. The fingers may be clubbed.

Splenic Anæmia has been discussed under ANÆMIA (p. 49). The spleen is not as a rule very greatly enlarged, though sometimes it may be enormous (*Fig. 611*). The blood-changes are simply those of progressive and severe anæmia of a chlorotic type : even though there may really be a disease meriting the distinctive term 'splenic anæmia', not a few cases diagnosed as such on account of the co-existence of splenic enlargement with simple anæmia ultimately turn out to be cirrhosis of the liver. When that which is really cirrhosis of the liver is diagnosed in its early stages as splenic anæmia, the condition is termed *Banti's disease*, though the cirrhosis, it would seem, is often due to some other cause than alcohol : the actual cause as a rule not being ascertained. One particular

variety of familial splenic anaemia of young persons has been distinguished from the rest as *Gaucher's disease*. It runs a course very similar to that of familial acholuric jaundice (see below), but is distinguished during life by the occurrence of a peculiar fat-like deposit under the exposed part of the conjunctiva external to the cornea; and after death by the presence of special 'glassy' Gaucher cells in the spleen and liver. It is rare.

Pseudo-leukæmia Infantum (von Jaksch's disease) was until recently regarded as, apart from true leukaemia, almost the only cause of very great enlargement of the spleen in young children (*Fig. 67*, p. 50). It is diagnosed by the severity of the anaemia, which is of the indeterminate chlorotic type without great leucocytosis, but with all the changes that are to be expected in any severe anaemia (p. 27) developing in an infant or young child, running a chronic course, but sometimes resulting in complete recovery. It is probable that von Jaksch's disease (splenomegaly and anaemia in a child) is not a disease but a syndrome, and that it includes cases in which these symptoms are due to different causes; in some this is congenital syphilis, as proved by Wassermann's test; others with a negative Wassermann reaction are probably related to the splenic anaemia of adults; others are familial acholuric jaundice; others, splenomegalic cirrhosis; others, Gaucher's disease; while some are of obscure types that have not yet been differentiated from the rest.

Still's Disease is really subacute generalized rheumatoid arthritis of children (*Fig. 381*, p. 472) associated with wasting, moderate enlargement of most of the superficial lymphatic glands, and in some cases, though not in all, considerable enlargement of the spleen. It is the affection of the joints that attracts chief attention; the patient may be completely crippled.

Familial Acholuric Jaundice is in many respects similar to splenomegalic cirrhosis of children, described above; without laparotomy or post-mortem examination it may be impossible to be certain whether or no the enlarged spleen is accompanied by cirrhosis. The disease may occur in a single member of a family, but more usually it affects brothers and sisters, runs a chronic course, beginning soon after birth but permitting of survival for many years. The patient might be described as delicate rather than ill, with more or less anaemia of chlorotic type, a facies reminiscent of that of pernicious anaemia, no great wasting, a distinctly icteric tinge of the skin and conjunctivæ, without any bile-staining of the urine, which remains of a normal colour; considerable enlargement of the spleen and often of the liver also; some of these cases give a positive Wassermann reaction, others do not; the congenital syphilitic type is held by some to be distinct from true familial acholuric jaundice. There may be instances of the disease in which the fragility of the red cells remains normal, but a characteristic of many or most of the cases is that the red cells become laked by dilutions of normal saline that should not lake healthy red blood-corpuscles—undue fragility of the red cells. This fragility is tested by preparing a series of test-tubes containing salt solution in successive dilutions: 0·58, 0·56, 0·54, 0·52, 0·50, 0·48, 0·46, 0·44, 0·42, 0·40, 0·38, 0·36, 0·34, 0·32 per cent; a drop of the patient's blood is added to each, and the dilution at which laking occurs is noted. Normal blood does not lake readily in a dilution above 0·38, and may not lake even in this tube; in acholuric jaundice the laking may take place at 0·44 or even at 0·50. Splenectomy has cured a certain number of these cases.

Egyptian Splenomegaly is a disease affecting natives in Egypt, clinically similar to splenic anaemia, but thought to be due to infection by a protozoon not yet discovered, though perhaps related either to malaria on the one hand or to trypanosomiasis upon the other. It runs a chronic course for some years, but ends like cirrhosis of the liver with ascites, pyrexia, and cachexia unless the patient is cured by splenectomy before a late stage is reached. The spleen may be enormous.

Fig. 611.—splenic anaemia: photograph showing the outline of the spleen. There was severe chlorotic anaemia without leucocytosis; the patient died, and at the autopsy there was no cirrhosis of the liver.

2. Chronic Enlargement of the Spleen, the Enlargement being of moderate Size.—

It is clear that conditions which may sometimes produce great enlargement of the spleen must go through a phase in which the spleen is not yet enormous, and at this stage all those diseases that have just been discussed will come into the present group. The remarks made already need not be repeated here, however, for the diagnosis at the stage in which the spleen is yet only moderately big is arrived at in the way already described. A blood-count is essential in order to exclude or diagnose leukaemia; parasites may be discovered to account for malaria or kala-azar; and so on. The spleen is palpable in a considerable proportion of cases of *pernicious anaemia*, but it is seldom greatly enlarged, and the diagnosis is arrived at by finding the blood-changes described under ANÆMIA (p. 30). In none of the other diseases mentioned in the list above are the blood-changes themselves pathognomonic.

The spleen of a small child is often just palpable without there being any disease at all; if it is more decidedly enlarged, the first suspicion will be that it is due to *rickets* or *congenital syphilis*. The bony changes, quadrate head, beaded ribs, large epiphyses, exaggerated curves of the long bones, particularly of the legs, delay in the closure of the fontanelles, and the pot-belly, will suggest rickets; it should be added, however, that owing to the eversion of the lower ribs along a line corresponding with the attachment of the diaphragm, and known as Harrison's sulcus, the spleen often becomes unduly palpable in rickety children without being necessarily enlarged. Congenital syphilis may be suggested by a knowledge of the family history, by the occurrence of snuffles, of specific skin eruptions, and so forth; but in many cases the diagnosis will be one of surmise only, unless it can be confirmed by the specific serum reaction of Wassermann. *Pseudo-leukaemia infantum* has been discussed above; by some it has been regarded as in some way associated either with rickets or with congenital syphilis, or with both; but the most recent view is that it is due to some cause other than these, of a nature not yet known.

Hodgkin's Disease, when it is typical, is associated with considerable and progressive LYMPHATIC GLAND ENLARGEMENT (p. 471), especially those of the neck, and later those of the axillæ and groins, thorax and abdomen, together with moderate but seldom very great enlargement of the spleen: without any anaemia to begin with, but later with a progressive and ultimately severe anaemia of the chlorotic type, with all the changes mentioned on p. 27; without leucocytosis, or at any rate without great leucocytosis, and with nothing characteristic about the differential leucocyte count except that an occasional basophil cell or myelocyte may be seen. Hodgkin himself laid particular stress upon the changes in the spleen in this disease, but there can be little doubt that there are cases of a precisely similar nature in which there is much lymphatic glandular enlargement without enlargement of the spleen. An attempt is sometimes made to distinguish this type from that with splenic enlargement, by styling it lymphadenoma; but where lymphadenoma ends and Hodgkin's disease begins, and vice versa, is by no means settled. It would seem much more likely that there is every degree of acuteness and severity between extremes that are wide apart: those cases which have lymphatic glandular enlargement and a rapidly fatal ending without leucocytosis as their most prominent feature being styled lymphosarcoma; similar cases with the addition of enlargement of the spleen, but a fairly rapid fatal ending, being termed acute Hodgkin's disease; others again, with enlargement of the glands without enlargement of the spleen and with rather greater duration, being termed lymphadenoma; whilst precisely similar cases with enlargement of both spleen and glands, and a duration of anything between several months and several years, are termed ordinary Hodgkin's disease. One very important point to be realized about this disease is that the blood-changes in it are not pathognomonic even when they are severe.

There is a special type of Hodgkin's disease in which the temperature chart exhibits periodic remissions and exacerbations not unlike those of relapsing fever (*Fig. 566*, p. 708), though the intervals between pyrexial bouts are generally longer—about a month. This type of chart may be the main feature of the case, enlargement of the spleen or the lymphatic glands attracting little notice for the time being, though generally developing sooner or later; cases of Hodgkin's disease of this periodic-pyrexial type are spoken of as *Pel-Ebstein's disease*, though other pyrexial cases may show no such periodicity (*Fig. 612*).

Cirrhosis of the Liver, by the time it has ended fatally, is nearly always associated with a spleen that is bigger than normal as judged by post-mortem weights. Clinically

however, this enlargement can be made out only in a small proportion of the cases, and even in these the enlargement is seldom great. When, however, there is doubt as to the diagnosis, and cirrhosis of the liver seems to be a possible cause for other symptoms, such as HÆMATEMESIS (p. 366), ASCITES (p. 59), JAUNDICE (p. 405), the presence of chronic but not very great enlargement of the spleen, without affection of the lymphatic glands and without pathognomonic blood-changes, is an additional argument in favour of the diagnosis. On the other hand, splenic enlargement is a very prominent and relatively

Fig. 612. Prolonged pyrexia in a case of Hodgkin's disease (lymphadenoma); there are waxings and wanings, but only slight indications of the pronounced periodicity of the pyrexia seen in the Pyl-Ebstein type of this disease.

early feature in a few cases, as in the splenomegalic cirrhosis of children (p. 466) and young adults; whilst in some older patients, long before the hepatic changes themselves attract attention, the case may come under observation for anemia, with or without hæmorrhage, such as purpura, epistaxis, hæmatemesis, or the passage of blood per rectum; and a considerable enlargement of the spleen may be found. The blood-changes may be merely chlorotic, and in the absence of other definite signs or symptoms the diagnosis of splenic anemia, that is to say, of simple anemia associated with an enlarged spleen, may be made; many such cases ultimately turn out to be examples of cirrhosis of the liver—Banti's disease.

Though there may be no pathognomonic blood-changes in cirrhosis of the liver, one feature of the fresh blood may be striking, and that is the rapidity with which the red

cells form into rouleaux when a drop is watched under the microscope: it is not a constant phenomenon, but it has served sometimes to establish the diagnosis. Rouleaux formation may be more immediate in some cases of cirrhosis of the liver than in any other condition. Urobilinuria (p. 902) is another phenomenon that is common in cirrhosis cases.

Lardaceous Disease. A lardaceous spleen is not always large, but is frequently big enough to be palpable, and the liver is generally enlarged at the same time. The condition results from long-continued suppuration, discharging sinuses from empyema or spinal caries, purulent cavities in phthisis or bronchiectasis, or from tertiary syphilis. If considerable enlargement of the spleen is associated with any of these it is probably due to lardaceous disease. There is generally diarrhoea on account of affection of the intestines: and polyuria and albuminuria owing to renal changes. The patient is weak, frail in aspect, and bloodless—often looking almost like a case of pernicious anaemia. Blood-counts exclude leukaemia, and indicate anaemia of the chlorotic type. The disease is far less common than formerly because modern surgical methods have done away with much of the persistent suppuration that was formerly common: for the most part it is diagnosed by reason of there being obvious cause for it, especially prolonged sepsis or tertiary syphilis.

Thrombosis of the Portal Vein as a cause of splenic enlargement can seldom be more than guessed at (see ASCITES, p. 67).

Pressure on the Portal Vein by enlarged lymphatic glands or by adjacent tumours will almost certainly be associated with obstruction to the bile-duct at the same time, so that there will be jaundice, and probably also ascites, in addition to any splenic enlargement: the latter will be slight.

II. ACUTE ENLARGEMENT OF THE SPLEEN.

1. Acute Infectious Fevers.—*Typhoid Fever* is the best-known febrile disease in which moderate enlargement of the spleen occurs. The organ is usually soft, so that often only an increased sense of resistance is noted on palpating close under the left ribs. The enlargement may be so slight that the organ is felt only when the patient takes a deep breath, so as to push it down from under the ribs: or it may be so big that its lower border reaches the level of the umbilicus. If, in a case of obscure fever in which a continued pyrexia (*Fig. 545*, p. 689) is associated with a relatively slow pulse-rate, the spleen is found to be enlarged, the diagnosis of typhoid fever is likely: especially if there is a history of gradual onset with anorexia and lassitude, accompanied by headache and sometimes epistaxis, a gradual rise of temperature which, if it has been observed from the first, is seen to go up about two degrees every night, with a fall of one degree the following morning, until step by step it reaches 103° F. or 104° F., or even higher: and perhaps no definite abnormal physical

signs whatever except as regards the spleen, or a few rhonchi in the chest. The characteristic rash does not appear until the sixth day or later, when it comes out on the abdomen, sometimes also upon the chest and back, in the form of small, rosy-red, flattened papules which fade on pressure, come out in successive crops, and are seldom present to the extent of more than half a dozen or a dozen at a time. Widal's agglutinating serum reaction should ultimately be positive in a dilution of 1 in 200 in half an hour, but it is generally the second week before this test is positive. Earlier confirmation of the nature of the fever may be obtained by the blood-count, there being no leucocytosis—indeed sometimes LEUCOPENIA (p. 454)—whilst, unlike many febrile illnesses, typhoid fever produces a relative increase, not in the polymorphonuclear cells, but in the small lymphocytes. Such blood-changes are in themselves almost pathognomonic, and they are obtainable before Widal's reaction is to be expected, though the latter is the ultimate test of the fever. Typhoid bacilli may be recovered from the blood on special cultivation quite early in the attack, but this method of diagnosis is not resorted to often. When neither blood-count nor serum-test is possible, the diagnosis may not be cleared up until the third week or later, when sloughs from Peyer's patches can be discovered in the stools. The ratio of the pulse-rate and temperature is of considerable value in the diagnosis, for in most cases the pulse-ratio is very low: for instance, with a temperature of 104° F. the pulse-rate may be only 90 or 100 per minute, when the physiological ratio for this temperature is 120.

Pneumonia in its earlier stages may also produce a low pulse-ratio: but the respiration-ratio is here increased, which is not the case in typhoid fever. The following figures illustrate these points:

				T.		P.		R.
Physiological ratio	104 F.	..	125	..	32
Typhoid fever	104 F.	..	90	..	30
Pneumonia	104 F.	..	100	..	40

General tuberculosis may simulate typhoid fever in this respect also, and sometimes it is not possible to decide between the two until the case has been watched for some time.

Paratyphoid Fever is closely related to typhoid fever, and the clinical symptoms are very similar: the importance of distinguishing between the two lies chiefly in the carrying out of Widal's agglutinating serum reaction. It sometimes happens that in a case which, from a clinical point of view, is almost certainly typhoid fever, the serum will not cause clumping of Eberth's typhoid bacilli: and so far as the bacteriological test goes the diagnosis might remain altogether obscure unless the serum were tested also against the *Bacillus paratyphosus A* and *paratyphosus B*. In a certain proportion of cases clumping will be obtained with one or other of these, the diagnosis of paratyphoid fever being based upon bacteriological rather than upon clinical conditions. The spleen is enlarged in paratyphoid fever to about the same extent as in typhoid.

Relapsing Fever is associated with considerable enlargement of the spleen. The disease is contagious, but nowadays rare, developing only under conditions of filth and famine. It is characterized by an acute onset, with chills, pains in the back, and a sudden rise of temperature. The latter remains high for six or seven days, and then falls by crisis. For about a week the temperature remains normal, and then it rises again as before, several such remissions and relapses succeeding each other and being pathognomonic of the disease (*Fig. 48*, p. 36). The pulse is rapid, and there is profuse sweating. Enlargement of the spleen is detected early. It is distinguished from other diseases by examination of blood-films, in which the *Spirochæta obermeyer* (*Fig. 606*, p. 779) should be found.

Malta Fever is discussed on p. 691: the splenic enlargement is similar to that of typhoid fever, and the diagnosis, suggested by geographical considerations, is confirmed by the specific serum agglutination test with the *Micrococcus melitensis*.

Malaria. Apart from the chronic enlargement of the spleen due to recurrent attacks of malaria the spleen becomes enlarged and soft as the result of active hyperæmia during acute attacks. Even when no splenic enlargement can be detected in the intervals, during the paroxysms the viscus can usually be felt projecting below the costal margin, presenting a soft and indefinite lower border. When the patient has more or less chronic enlargement of the spleen as the result of preceding attacks, each acute febrile paroxysm is associated as a rule with an additional swelling which passes off after the attack. For the characters of the fever, see pp. 37-42. The nature of the malady will be suggested by geographical considerations, or by the influence of quinine: but the only conclusive proof is the discovery in stained blood-films of the malaria parasites (*Figs. 57-60*, pp. 40, 41). There is often marked anæmia, especially in cases of recurrent malaria, the red corpuscles and hæmoglobin becoming reduced as in chlorosis: the leucocytes are also diminished, and the differential leucocyte count shows a relative increase in the large hyaline lymphocytes up to even 15 or 20 per cent.

Erysipelas is often associated with moderate enlargement of the spleen: but the fever (*Fig. 556*, p. 699), rigors, and slightly-raised red spreading infection of the skin are sufficiently characteristic to indicate the diagnosis.

Septicæmia may be less easy to diagnose unless there is some obvious source of sepsis in the first instance, such as infection of the uterus after childbirth, sepsis in connection with the general peritoneal cavity, joints, wounds, and so forth. The chief difficulty arises in those cases in which the source of the sepsis is not obvious, being due to absorption from such lesions as pyorrhæa alveolaris, septic tonsils, infected nasal sinuses, whitlows, æne or other comparatively small superficial affections: or to deep-seated suppuration, such as a hidden empyema, infective pylephlebitis, infective cholangitis, pyosalpinx, and so forth. In some cases of chronic or subacute septicæmia enlargement of the spleen may be considerable, and the diagnosis of infective endocarditis will very likely suggest itself.

Whether or not the heart valves are affected in these cases, the ultimate diagnosis will depend upon discovery of infective organisms in blood-cultures obtained by venepuncture.

Trench Fever, a louse-borne disease that was very common in the great war, is now happily rare : starting as an acute febrile illness similar to influenza, it is liable to become chronic, with general ill health, recurrent irregular pyrexial bouts, pains and aches in various parts, with predominance of severe shin pains, various signs of disordered action of the heart, especially tachycardia, breathlessness on exertion, precordial discomfort or pain, and a liability to ready fatigue, so that, try as the patient will, he finds himself worn out before the day's work is half done. During the ordinary acute attack the spleen is nearly always palpable : it regains its normal size during remissions, but enlarges to become palpable again during recurrent exacerbations. There is no ready clinical criterion

Fig. 613. Temperature chart from a typical case of typhus fever ending by lysis rather than by crisis. (Chart kindly supplied by Dr. Turner, Medical Superintendent of the South Eastern Fever Hospital, London.)

of the diagnosis, but the latter may be suggested by the symptoms and by the circumstances of a case, especially if life has been led under conditions that imply lousiness.

Diphtheria, *Pneumonia*, *Scarlet Fever*, and *Small-pox* seldom give rise to very prominent splenic enlargement, and the only importance of it is that in the early stages of the malady detection of a spleen that is just palpable may temporarily arouse a suspicion that the patient is suffering from typhoid fever. The course of the disease, bacteriological examination of swabbings from the throat, the physical signs in the lungs, and characters of the sputum and the skin rash, will serve to point to the correct diagnosis.

Fig. 614. Case of typhus fever, showing termination by crisis at the end of the second week. The majority of the cases exhibit a less abrupt ending to the pyrexia perhaps, but the above type is characteristic in some epidemics. (Chart kindly supplied by Dr. Turner, Medical Superintendent of the South Eastern Fever Hospital, London.)

Typhus Fever is fortunately very rare now, although there are small outbreaks of it in the poorer parts of large cities from time to time : the spleen becomes soft and moderately enlarged, but less constantly so than in typhoid fever. The disease sets in more acutely than enteric, with chills, early prostration, and a high temperature, which ends by less marked lysis (Fig. 613) than does that of typhoid fever (Fig. 545, p. 689), and sometimes almost by crisis at the end of the second week (Fig. 614). The rash differs from that of typhoid fever in that it appears on the fifth day, and consists of petechiae and of dark-red groups of subcutaneous macules in addition to rosy-red papules on the surface (see Fig. 327, p. 418). Nervous symptoms become very marked, especially at the end of the first week, the so-called typhoid state being an expression used to denote, not the condition that occurs in typhoid fever, but that which develops in typhus. There may be severe vomiting, and retention of urine, important symptoms that are rare in typhoid fever. There should be no positive Widal's reaction, and no sloughs in the stools.

Influenza is a diagnosis which should never be made except with very good cause, for many febrile illnesses in which the real cause escapes recognition receive the label *influenza*. It is easiest to diagnose correctly in times of severe epidemic, and then slight enlargement of the spleen may occur in a few cases. This in itself is not important if *influenza* can be diagnosed with certainty on other grounds; but until the nature of the fever becomes obvious it is important in that it may suggest typhoid when none exists. The sudden onset, extreme prostration, high pulse-rate as well as temperature, initial chill, profuse sweating which comes on when the patient begins to improve, and the fall of the temperature after an illness lasting from twenty-four hours to three or four days or a week, would all point to *influenza*. It may, however, be impossible to distinguish *influenza* from typhoid fever until the course of the pyrexia has been watched, or unless typical *Bacilli influenzae* are recovered in nearly pure culture from some secretion, such as the sputum. It is worthy of note that in *influenza* as well as in typhoid there is no leucocytosis.

General Tuberculosis may also simulate typhoid fever in certain cases, and enlargement of the spleen may result from the development of tubercles in it. When cerebral symptoms predominate the diagnosis is relatively easy: the headache may be equally severe in both, but with tuberculous meningitis there is more vomiting and more retraction of the head, whilst optic neuritis, and perhaps choroidal tubercles, may be detected. *Widal's* test will remain persistently negative: there will be no rosy rash, probably no leucocytosis, and no sloughs will be found in the stools. In some cases, however, general tuberculosis produces a clinical picture that may be very difficult to distinguish from typhoid fever. Lumbar puncture may decide the diagnosis.

2. Embolism. Fungating endocarditis is nearly always associated with palpable enlargement of the spleen, and sometimes the organ attains a considerable size (*Fig. 615*). Ordinary heart disease with failure of compensation does not give rise to splenic enlargement that can be recognized clinically, except perhaps in children, notwithstanding the fact that one might have expected the backward pressure to cause the spleen to be big by being dilated with blood. Except in children, enlargement of the spleen in a heart case should always arouse serious suspicion of infective endocarditis. The enlargement may be due to embolism and infarction, in which case there may have been a history of acute pain low down on the left side of the chest, accompanied by a definite rub due to perisplenitis over the infarct. The splenic enlargement in some cases, however, is due less to actual infarction than to the general toxæmia; even when there has been an infarct it is not always easy to be sure of it. Fungating endocarditis sometimes develops without there being any bruit at all; the diagnosis is then exceedingly difficult unless the patient suffers from multiple emboli cerebral, renal, intestinal, splenic, peripheral. Sometimes such an embolus may be followed by the development of an acute aneurysm—femoral, popliteal, cerebral, and so forth. A cerebral embolism of this kind has sometimes resulted in sudden transient coma and hemiplegia: the patient has seemed to be recovering; then in a day or two has relapsed into coma again, and died, the cause of the relapse and fatal ending being the development of an acute cerebral aneurysm at the site of the embolus, rupture of this aneurysm, and death from the resultant hæmorrhage. Progressive anæmia of the chlorotic type, without much leucocytosis, is another feature of these cases. The diagnosis must always be difficult when there is no cardiac bruit; when there is a bruit, the difficulty is to determine whether the patient is suffering merely from mechanical heart-failure or from fungating endocarditis superposed upon the chronic heart lesions (p. 45).

Fig. 615. Photograph showing great enlargement of both the spleen and liver in a case of fungating endocarditis (the same patient as in *Fig. 549*, p. 678, illustrating purpura). Note also clubbing of the thumb and fingers just discernible in the left hand. The diagnosis was verified at autopsy.

Thrombotic infarction may cause acute splenic enlargement in almost any of the blood diseases, particularly in lymphadenoma and leukaemia.

3. Injury; or Strangulation by Twisting of the Pedicle.—Neither injury nor strangulation of the spleen by its becoming twisted upon its own hilum is a very common event, and the latter is nearly always the result of injury. A blow in the splenic region may cause a rupture in the pulp of the spleen without bursting its capsule, and without obviously injuring the chest wall or abdomen. The bleeding that occurs within the capsule of the spleen itself causes great pain in the part and enlargement of the organ: the diagnosis can seldom be more than guessed at unless laparotomy is performed. Strangulation of the spleen seldom occurs if the organ is in its natural position: but when there has been previous dislocation, an abdominal injury, or sometimes a sudden spontaneous effort, has led to its becoming twisted on its own hilum, the symptoms being such as to suggest an acute intra-abdominal condition requiring immediate laparotomy, but seldom pointing to the actual diagnosis until the laparotomy has been performed.

Herbert French.

SPONGY GUMS. (See BLEEDING GUMS, p. 93.)

SPUTA vary enormously as to their amount, consistence, colour, and smell: but by far the most important point about them in diagnosis is the determination of whether they contain tubercle bacilli or not.

Sputum in Pulmonary Tuberculosis.—There is no particular variety of sputum which can be said to be characteristic of pulmonary tuberculosis, although stress is generally laid upon the fact that phthisis with cavitation produces a nummular sputum—that is to say, sputum of which the individual portions expectorated tend not to coalesce but to flatten out as separate round portions if they are spat on to a flat, dry surface—like separate combs in a heap: if expectorated into antiseptic fluid they remain as more or less globular, separate masses. As a matter of fact, however, ordinary bronchitis may produce sputum possessing a typical appearance of nummularity, and it is most unwise to rely on the naked-eye appearances of sputum for any diagnosis except that of lobar pneumonia, when it may be typically viscid and rusty. It is in almost all cases essential to make films of the sputum, and to stain these for tubercle bacilli by the Ziehl-Neelson method with carbol-fuchsin.

The carbol-fuchsin solution is made up of 1 gm. of fuchsin, 10 c.c. of absolute alcohol, and 100 c.c. of 5 per cent solution of carbolic acid in distilled water. The slide, upon which a minute portion of the sputum has been spread out well and then fixed by passage two or three times through a Bunsen burner flame, is covered by the stain in a suitable receiver, and held over a small Bunsen burner or spirit flame until the fluid steams briskly but does not actually boil. After immersion in this for about five minutes, the excess of stain is poured off, the film washed in water, the excess of the latter drained off, and the slide immersed in 25 per cent sulphuric acid for about half a minute: it is then transferred to water again, and recovers more or less of the red tint of the fuchsin: if too little of this has been discharged, the slide is returned to the sulphuric acid for another period, and so on: when well decolorized, only the thickest parts of the film retain obvious red: it is then counterstained by five minutes' immersion in carbol-methylene blue, the excess of this stain being washed off with water, the film dried in the air, and either mounted in Canada balsam or else examined directly under the oil-immersion lens: tubercle bacilli (*Fig. 607*, p. 779) show up as bright-red rods in a blue field.

The presence of acid-fast bacilli in an ordinary sputum film is very nearly proof positive of tuberculosis of the lung, the only source of fallacy being the possibility of non-pathogenic acid-fast bacilli being derived from the mouth. It is very unlikely that this source of fallacy will persist from day to day, especially if care be taken to make the films from the interior of the sputum pellets. It should be remembered, of course, that the absence of tubercle bacilli, or rather their non-detection, is no proof of the absence of pulmonary phthisis, and if there is doubt successive sputa should be tested in the same way. It should also be remembered that a lesion which may have been tuberculous originally may in time lose its tuberculous character: the tubercle bacilli may die out, though the cavities produced by them still persist and become occupied by pyogenic organisms and their products. Many of the symptoms of phthisis itself are not due to tubercle bacilli directly, but rather to secondary infection by streptococci, staphylococci, pneumococci, *Micrococci catarrhales*, Friedländer's bacilli, and so forth: and the degree

of this secondary infection may be gauged by having the sputa cultured by special bacteriological methods.

It is also important to examine for elastic fibres—a procedure that is resorted to far too seldom. A person may expectorate sputum containing tubercle bacilli every day for months and yet may have precisely as much lung tissue left by the end of that time as at the beginning: this is due to the fact that when cavities have been produced they are lined by granulation tissue, and these granulations may produce a continuous supply of tubercle-containing sputum without progressive erosion of lung tissue, precisely as some skin ulcers may discharge abundantly and yet remain the same size for months. The best evidence of lung destruction is afforded by the discovery of elastic fibres (*Fig. 616*) in the sputum: if these are present there must be erosion of lung tissue, and if tubercle bacilli are present at the same time the two together indicate advancing phthisis. The elastic fibres may be obvious under the microscope when ordinary sputum is examined fresh after it has been pressed out between cover-slip and slide, but oftener they are more easily detected when a quantity of sputum has been boiled with strong caustic soda to destroy pus cells and mucus leaving the resistant elastic fibres unaffected. Tubercle bacilli are also resistant to strong alkali, and when they are suspected but cannot be found without in some way concentrating them, it is a useful plan to boil the sputum with an equal amount of 5 per cent caustic potash, or with antiformin, to dilute the result with water, to centrifugalize it well, and make films from the deposit. There are various other methods of obtaining concentrated bacilli from the sputum, but this is one of the simplest. It should be borne in mind that tubercle bacilli may be found even when the sputum is exceedingly small in amount and apparently insignificant and mucoid.

Fig. 616. Elastic fibres from sputum. The alveolar arrangement exhibiting an alveolar arrangement of the fibres.

For sputa containing blood, see HÆMORRYSIS (p. 358).

Viscid, Rusty Sputum is almost pathognomonic of pneumonia. As a rule the diagnosis of lobar pneumonia is fairly clear owing to the sudden onset of an acute

Fig. 617. Temperature chart of an ordinary case of lobar pneumonia, showing a crisis on the seventh day of the illness, and a slight post-critical rise on the following day.

pulmonary complaint associated with fine crepitations confined to one or more lobes, followed by dullness, with bronchial breathing, bronchophony, and pectoriloquy without râles: these being succeeded by redux crepitations, with a diminution in the bronchophony, pectoriloquy, and bronchial breathing until normal voice and breath-sounds are restored. Herpes labialis is common. The patient's temperature, after maintaining a high level such as 103° F. or 104° F. for from five to ten or more days—usually about seven—falls by crisis (*Fig. 617*). The respiration-rate is very rapid—for example, 40 per minute—during the height of the fever, and the skin is flushed, dry, pungent before the crisis, moist from profuse perspiration after it. The diagnosis is much more difficult in some cases, however: there are not a few patients in whom the consolidation is

deep-seated so that it does not come to the surface at all, and lobar pneumonia has to be diagnosed when no abnormal physical signs have been detected in either side of the chest. In such cases the general symptoms may suggest the diagnosis, and the sticky, viscid sputum, the colour of which is generally that of iron rust but which may be any of the colours that a bruise may have, from bright-red or brown to greenish-brown, greenish, yellowish, or even bluish-yellow confirms it even when the lung signs remain normal. The viscosity of the sputum in these cases is of as much importance as the colour. Films of it usually contain numbers of pneumococci: in exceptional instances pneumobacilli. When lobar pneumonia is due to the influenza bacillus the sputum has not the viscid, rusty character as a rule, but is more like that of ordinary mucopurulent bronchitis, though in the pulmonary form of influenza it may be blood-stained. The presence of pneumococci, however, or of any micro-organism other than the tubercle bacillus, is by itself no proof that these are the cause of the lung lesion, for the sputum of perfectly normal persons often contains pneumococci, streptococci, and other bacteria. It is quite possible for a patient who is dying of general miliary tuberculosis of the lung to have no tubercle bacilli in the sputum, but an abundance of capsulated pneumococci which may readily, when they are discovered, lead to an erroneous diagnosis.

Sputum in Influenza. Influenza bacilli are exceedingly small: but it is important that they should be looked for, both directly and by cultural methods, in all cases thought to be influenzal, before this diagnosis is regarded as established: even when influenza bacilli are found there is still the possibility that they may be an intercurrent infection in some other malady: but it is so tempting to think of influenza when no other obvious cause for a febrile illness can be discovered, that it should not be diagnosed until influenza bacilli have been shown to be present. There is a tendency nowadays to discount the causal relationship of Pfeiffer's *Bacillus influenzae* to influenza, and to attribute the latter to invisible filter-passing organisms, but the facts are still *sub judice*: what is remarkable, on the other hand, is the ease with which Pfeiffer's bacilli may be missed even on culture when they are really present in large numbers: and personally I regard their discovery as important in the diagnosis of true influenza cases.

Abundance of Foul Sputum, especially when expectorated much at a time at comparatively long intervals, is sometimes by itself a striking symptom, and it suggests that the patient is suffering from one or other of the following:

Bronchiectasis	Gangrene of the lung
Phthisis with cavitation	Hepatic abscess ruptured into
Fetid bronchitis	Subdiaphragmatic abscess the lung.
An empyema ruptured into the lung	

It is sometimes very easy to distinguish between these: with *fibroid lung and bronchiectasis* the patient is likely to have had symptoms periodically for a long while: there will generally be CLUBBED FINGERS (p. 142): the abnormal physical signs are confined to one lung as a rule, and especially to the lower lobe, with displacement of the heart towards that side: there will be deficiency of movement, resonance, and vesicular murmur in the affected lower lobe, together with either absence of voice-sounds and of râles, or scattered foci of crackling râles, especially when the patient coughs, with bronchophony, pectoriloquy, and bronchial breathing. If, on the other hand, the abundant and foul sputum is associated with abnormal physical signs in both lungs, and if the upper lobes are obviously more affected than the lower, if the patient has a strong tuberculous family history, and if tubercle bacilli are either now present in the sputum, or are known to have been present formerly, the diagnosis of *chronic phthisis with extensive cavitation and secondary infection of the cavities* with pyogenic organisms is obvious.

Fetid bronchitis is always a dangerous diagnosis to make, and the probability is that many cases so diagnosed have been examples either of deep-seated bronchiectasis, of phthisis with cavitation and secondary pyococcic infection, or of *empyema ruptured into the lung*. The latter is sometimes associated with hardly any abnormal physical signs, because if the original empyema had given rise to the ordinary signs it would have been diagnosed and relieved by operation: an empyema may develop either between the lobes, or between the pericardium and the lung, or between the diaphragm and the lung, in such a way as to leave normal lung tissue all round the surface next the chest wall, so that the

usual evidence of pus in the chest is entirely wanting. Even if abnormal physical signs are produced when the pus is kept in an abnormal position in this way the needle may have to pass through so much tissue before the empyema cavity is entered that the pus cannot be located: in either of these cases the empyema will, in the course of time, tend to ulcerate its way through the pleura and lead to the expectoration of large quantities of foul sputum at intervals as the empyema cavity re-fills. The diagnosis depends largely upon the exclusion of other causes of abundant foul expectoration, and perhaps upon the history of a preceding illness predisposing to empyema, for example lobar pneumonia: especially if the patient is clear that up to a particular date he had been troubled by cough and chest trouble of some kind without particular expectoration, and then one day, after a bout perhaps of specially severe coughing, brought up a small cupful or more of foul material which had recurred at intervals ever since: the first bout of foul expectoration corresponding to the time when the buried empyema ulcerated its way through the pleura and became evacuated through a bronchus.

Gangrene of the lung may be simulated to some extent by bronchiectasis or by empyema rupturing into the lung: but generally speaking nothing but gangrene will produce so much stench. Foul though the sputum in bad bronchiectasis may become, it seldom approaches the awful fetor of pulmonary gangrene. The history, moreover, is acute: there may be some obvious cause for gangrene, particularly lobar pneumonia in a patient debilitated from some other cause, such as diabetes, or inhalation of foul particles after immersion in a dirty river, or as the result of disease of the mouth, throat, or œsophagus, or septic embolism of the lung from lateral sinus thrombosis. If any doubt remains as to whether lung tissue is being destroyed or not, elastic fibres can be sought for, their presence at once distinguishing between bronchiectasis or deep-seated empyema on the one hand and gangrene on the other.

When a large quantity of pus is expectorated through the lung in a person who, having been in the tropics and having possibly suffered from dysentery, has since had symptoms pointing to hepatic trouble, the possibility that an amœbic abscess of the liver may have opened its way through the diaphragm into the lung will occur to one, especially if the expectorated pus is tinged the colour of anchovy sauce. It might be thought that the *Amœba coli* would be found in it: this protozoon is not present in the pus of a hepatic abscess as a rule, however, but only in the granulations of the abscess wall. The sputum in these cases is not generally foul.

Purulent sputum, often free from unpleasant odour, and not necessarily abundant, is common to almost any form of bronchitis after the initial serous stage has passed, in which the sputum is white and frothy: occasionally a much severer state of affairs is met with, with pyrexia, marked cyanosis, much cough, and an abundance of purulent phlegm *purulent bronchitis* which may simulate lobar pneumonia in its severity and exceed pneumonia in its mortality. These cases are probably sporadic instances of that which was called the dread *influenzal pneumonia* of the great epidemic. The sputum generally yields influenza bacilli plus some other pyogenic germ of virulence, so that one has influenzo-pneumococcal cases, influenzo-streptococcal cases, influenzo-pneumobacillary cases, all presenting a similar clinical picture and an abundance of sputum which, if it is not hemorrhagic, looks more or less like pus.

The other abnormal features that may be exhibited by sputum are relatively uncommon, and are of diagnostic significance only in exceptional cases. The serous, mucoid, mucopurulent, or purulent sputum of the various stages of acute and chronic *bronchitis* may arouse a doubt as to whether the patient has not a tuberculous focus: repeated examination will fail to reveal either tubercle bacilli or elastic fibres, but it is to be remembered that a considerable minority of phthisical subjects seem not to expectorate the bacilli. *Black sputum* is common in those who live in smoky atmospheres, particularly in towns, colliery districts, and manufacturing centres. Other changes in colour may be due to hæmoptysis, pneumonia, or hepatic abscess, which are all discussed above: sometimes infection by the *Bacillus pyocyaneus* may produce greenish or bluish sputa which may alarm the patient, but which need not have any serious import, and red sputum simulating the hæmoptysis of phthisis may be due to infection by pigment-producing bacilli such as the *Bacillus prodigiosus*: phthisis may be diagnosed wrongly in such a case unless the most careful investigations of the sputa are made by cultural methods.

CURSCHMANN'S SPIRALS (p. 191) and CHARCOT-LEYDEN CRYSTALS (p. 131) have been discussed elsewhere.

Casts of the bronchial tubes are met with in very exceptional cases, and they are of two main types—namely, diphtheritic and non-diphtheritic. The distinction depends on bacteriological examination: histologically they consist of ill-defined exudate containing cells irregularly embedded in it. Non-diphtheritic casts are due to plastic or fibrinous bronchitis, a very rare disease of which the sputum is the diagnostic point. Two other rare causes for the expectoration of casts of the bronchi are lobar pneumonia, and the inhalation of blood from some other part of the lung in a case of hæmoptysis, and its subsequent expectoration after it has clotted.

Now and again a *cretaceous pellet* (Fig. 618) or a small *caseous mass* may be found in the sputum either of a patient who has pulmonary phthisis, as evidenced by the abnormal apical physical signs and by the detection of elastic fibres as well as tubercle bacilli in the sputum, or in children as the result of the ulceration of a caseous bronchial gland into the trachea or a main bronchus and then expectoration of its caseous or cretaceous contents.

Fig. 618. --- Calcareous concretions from phthisical sputum.

Chalk-white sputum floating upon the top of any disinfectant liquid into which it has been expectorated has no constant causation, but it is seen most commonly, perhaps, when there is epithelioma of the œsophagus causing stenosis of the latter and leading to irritating cough by reason of the mucus and food particles which keep rising from the obstruction toward the larynx: the sputum is not truly pulmonary, but consists of a mixture of mucus, phlegm, food remnants, and altered milk: the patient coughs it out, however, and its appearance may be remarkable.

Another rarity which has occasionally been found in the sputum is a recognizable particle of *new growth*, the detection of which may be of material assistance in diagnosis.

Chemical analyses are relied on by some observers in distinguishing tuberculous from non-tuberculous sputum, it being stated that expectoration containing coagulable protein is more likely to be the result of tuberculous infection than is sputum which does not coagulate with heat. This distinction, however, is not universally accepted, and microscopical examination for tubercle bacilli is certainly a more reliable test in the great majority of cases.

The rarer bacteria and moulds that may be detected in the sputum by special bacteriological methods generally require very special investigation, including cultural tests by skilled bacteriologists: one need not, therefore, enter into details here, though it may be well to enumerate certain micro-organisms which may be pathogenic in the lung in comparatively rare instances: *B. mallei*, generally amongst workers in stables or otherwise in connection with horses: *Aspergillus flavus*, *A. niger*, *A. fumigatus*, generally amongst those who have to do with the artificial feeding of pigeons and other birds: *Actinomyces*, or the ray fungus, in those who have had to do with barley in some way or another, or those who are in the habit of holding cotton in their mouths, such as tailors and seamstresses. Besides these pathogenic micro-organisms, not a few others which are not actually pathogenic are to be recognized in the sputum when it has become secondarily infected in chronic cases: *Penicillium glaucum*, for instance, or *Oidium albicans*: yeast and other moulds: *Micrococcus tetragenus*: or *Oidium tropicale*, a micro-organism similar to but culturally different from *Oidium albicans*, which has recently been reported to be a cause of lung lesions both in Europeans and natives in Ceylon, the symptoms suggesting phthisis, but the latter being excluded by the persistent absence of tubercle bacilli from the sputum and by the absence of reaction to tuberculin.

The lung fluke, *Paragonimus Westermanni*, which causes hæmoptysis in Korea, Japan, and parts of China, is to be diagnosed by the discovery of its oval, capsulated eggs in the sputum.

Herbert French.

SQUINT.—(See DIPLOPIA, p. 220; and STRABISMUS, p. 797.)

STAMMERING.—(See SPEECH, ABNORMALITIES OF, p. 774.)

STERILITY. The differential diagnosis of the causes of sterility is often difficult, and although there are many well-defined conditions which give rise to it, there are numbers of cases in which no definite cause can be found. Further, we must not overlook the fact that the husband is responsible for a sterile marriage in one-fourth to one-third of the cases. This is a fact shown by many observers, and too often forgotten when investigations are made. Therefore we must not consider a case to be complete unless the husband and *his semen* have been investigated. Many a woman has her married life made miserable, and is taken from doctor to doctor on account of sterility, when really the husband is to blame.

The causes of sterility are shown in the following table :—

LESIONS OF THE GENITAL ORGANS		GENERAL CONDITIONS
<i>Congenital Lesions :</i>	<i>Acquired Lesions :</i>	Old age
Absence of uterus, tubes, ovaries	Dyspareunia	Obesity
Closure of hymen, vagina, cervix	Vaginismus	Anamia
Pseudo-hermaphroditism	Salpingo-oöphoritis	Nutritional disturbances
Infantile uterus	Uterine fibroids	Incompatibility
Small adult type of uterus	Endometritis	Absence of sexual feeling.
'Cochleate' uterus	Cervical catarrh	
Displacements	Polypi	
Hypothetical changes in the endometrium.	Carcinoma of cervix	
	Carcinoma of fundus	
	Ovarian tumours	
	Acquired atresia of vagina	
	" " cervix	
	Genital fistulae	
	Hyperinvolution	
	Astringent douches	
	Deficient ovarian activity.	
	<i>In the male</i>	
	Azoospermia	
	Oligospermia	
	Necrospermia.	

A study of the above table shows that some of the causes of sterility are primary, whilst others are secondary. Thus absence of the uterus or infantile uterus means primary sterility, whilst hyperinvolution, carcinoma of the cervix, etc., may occur in women who have had children, and only secondarily become sterile on account of these lesions. Further, some of these causes are common, or may be remedied: others, on the other hand, are rare or absolutely incurable. Diagnosis is therefore of great importance, for it is far better to discover and remedy a defect early in married life, than to wait until the best years are soured and embittered by the longing for a child. Unfortunately, many patients, from various motives, put off the investigation too long.

Congenital Lesions. Some of the congenital lesions are diagnosed easily, such as *closure of the hymen, absence of the vagina, or closure of the cervix*, whilst absence of the essential organs often requires an anæsthetic in order that a bimanual examination may be made satisfactorily. The *infantile uterus* and *small adult type* are very difficult to differentiate; but in the former the body forms only one-third of the total length of the organ, whilst in the latter it forms two-thirds, both types of uterus being small in the antero-posterior and lateral dimensions, and only slightly shortened in the vertical. Of all the congenital lesions, the '*cochleate*' uterus of Pozzi is the commonest cause of sterility, and is the most hopeful as regards treatment. The uterus is felt to be unusually curved anteriorly, has a long conical cervix, and a small external os. In such an externally malformed uterus as this it is possible that the internal structure is abnormal; the endometrium, perhaps, is unduly thin and fibrous, the muscle layers badly developed. The hypothetical *change in the endometrium* may be the essential cause of sterility; hence curettage for its complete removal forms an essential part of the treatment. The peculiar shape and curvature have long been considered a possible cause, preventing the entrance of spermatozoa into the cavity. *Pseudo-hermaphroditism* usually shows itself by shortness of the vagina, elongation of the clitoris, and the presence of glandular masses in the groins, which are almost always testes, proving that the subjects of it are really undeveloped males.

Acquired Lesions. The differential diagnosis of the acquired lesions can only be made by complete examination of the patient by inspection, bimanual examination, and the use of the microscope to elucidate doubtful growths. *Dyspareunia* as a cause is dealt with under this heading (p. 239). *Hyperinvolution* is diagnosed easily: it occurs always after a labour, and strictly means a continuance and progressive increase of the normal luetation atrophy of the uterus: the latter is felt to be very small bimanually, and the sound may pass only 1½ inches in a marked case: it is always associated with incurable amenorrhœa.

Deficient ovarian activity, whereby the Graafian follicles do not ripen or rupture is not to be diagnosed by any of the ordinary methods we can employ, and it is doubtful whether a microscopic examination of the ovaries themselves would reveal the true condition. It is supposed to be associated with scanty menstruation or amenorrhœa for which no other definite cause can be found. Absence of ovarian activity must be the true cause in the general conditions which are outwardly shown by *obesity*, *anæmia*, and *disturbances of nutrition*: and it is a fact that some women have not conceived as long as they remain too fat, whilst loss of weight has in some cases been followed by conception. *Incompatibility* between husband and wife sexually is an ill-defined condition, which, however, is fully believed to be a cause of sterility. It is almost incapable of proof, for in the case of a sterile widow who remarries and conceives for the first time we have no proof that the former husband was capable of procreation. *Absence of sexual feeling* or the sexual orgasm, too, is not always a cause of sterility, for conception has occurred in women who are absolutely devoid of these feelings. On the other hand, most authors quote the case of a woman who conceived as a result of the only coitus at which an orgasm was experienced. The influence of *age* on child-bearing must not be forgotten, the liability to conceive falling rapidly every year over thirty.

Sterility of the Male. Finally, the examination of the husband and his seminal fluid should never be omitted unless there is some quite well-defined cause to be found in the wife. Assuming that the penis and testes are present, and that erections render the sexual act possible, the seminal fluid must be examined carefully. The fluid should be collected in a condom by means of a normal coitus, and should be examined within twelve hours. It must be spread on a slide and examined with a high power of the microscope. There may be no spermatozoa present at all, the condition known as *azoospermia*, in which case the husband is incapable of procreation. There may be but few spermatozoa, and those exhibiting only feeble powers of movement - *oligospermia*. There may be plenty of spermatozoa present, but quite devoid of motility - *necrospermia*. It is unnecessary in this article to enter into the causes of these conditions. They are usually incurable, and consequently further investigation is unnecessary. T. G. Stevens.

STERTOR is really another word for snoring: but it is commonly restricted to the heavy, snoring sound accompanying inspiration, produced not in the nose but by vibrations of the soft palate, generally when the patient is in a state of profound unconsciousness. It differs from stridor in that the latter is produced in the larynx. If, as is generally the case, the patient is comatose, the presence or absence of stertor helps little in the diagnosis, which is discussed under the heading *COMA* (p. 153). Sometimes, however, without being comatose, the patient may have stertor during sleep, when he is suffering from the effects of drink or from any of the following:

Adenoids

Hypertrophied tonsils

Quinsy

Paralysis of the soft palate

Postpharyngeal abscess.

The stertor in these cases is closely akin to snoring. The differential diagnosis generally becomes manifest when the interior of the mouth and the pharynx are examined. Possibly the condition most likely to be overlooked is postpharyngeal abscess, but this should not be mistaken for anything else if a digital examination of the back of the mouth is made: moreover, except when due to tuberculous caries of the cervical vertebrae, it is commonest in infants and quite small children, becoming rarer with each year of life.

Herbert French.

STIFF NECK. This occurs in a number of diseases entirely different in character, and its significance may be either grave or trivial. It is rarely that stiffness is the only symptom, but it may be the first thing complained of, or it may be a complication arising

in the course of a disease. It is not right to assume that the trouble is trivial, or vaguely to designate it as 'rheumatic', without a thorough investigation. It is necessary first to inquire into the history, when it may become obvious that it follows, say, an injury, or has arisen during the course of some disease, and is not primary. Next examine the patient with the head and shoulders bared, and see whether there is any swelling or abnormality present, also the extent of possible movement, and whether or not it is the movement that causes pain: if possible, locate the seat of the pain. Many further investigations may be necessary, e.g., examination of the throat for tonsillitis, the ear for suppurative otitis media, etc., according to the circumstances of the case: or the neck may need to be X-rayed to find out whether the vertebrae themselves are healthy or otherwise: a crack may be discovered in the body of one of the cervical vertebrae, especially the fifth or sixth, after an injury which may not seem to have been of sufficient violence to cause fracture of the spine.

Exposure to Cold or Sleeping in a Cramped Position may give rise to a transient stiff neck associated with no other symptoms. There is generally a distinct history of the patient waking up in the morning with a stiff neck, and the diagnosis is made by exclusion. Often, in such cases, there is a latent focus of microbial infection, especially in connection with a tooth: the stiff neck is a variety of fibrositis in these cases.

Inflammation of the Lymphatic Glands and the cellular tissues of the neck may cause local stiffness, whether the infecting focus be a boil or carbuncle, or a carious tooth, an inflamed tonsil, pediculosis capitis, or other similar cause. There is no spasm or rigidity of the muscles here, the neck can be moved quite well: but it hurts to do so, and therefore it is held stiffly. The diagnosis is easy as a rule.

Torticollis or *Wry-neck* is due to contraction of the sternomastoid muscle on one side, usually the result of an injury to the muscle caused by pulling on the aftercoming head in breech presentations. The muscle stands out as a tight band in the neck, and its contraction leads to a characteristic deformity. The head is pulled down towards the affected side, and the face and chin are tilted towards the opposite shoulder. The movements of the head are necessarily restricted owing to the shortening of the one muscle, and in long-standing cases this leads to a marked asymmetry of the face. The consequences are not limited to the head and neck, for the spine shares in the general obliquity, and shows marked lateral curvature in old cases.

Spasmodic Torticollis is an unusual form due to spasms of the sternomastoid and other muscles of the neck. The spasms are intermittent, coming on suddenly with great pain, the affected muscles relaxing after a variable time, and during sleep.

Cervical Caries. The greatest care must be taken not to confound muscular rigidity with tuberculous disease of the cervical vertebrae. In the latter, pain and rigidity are among the earliest signs: the pain is increased by the least movement, and the child—for it is generally a child that is affected—takes the greatest precaution to avoid any movement, even holding the head between the two hands. The position of the head varies: it is most often held very stiff and straight, the natural backward curve of the neck being lost. In the late stages there may be an angular or lateral curve. The distaste for movement is very well brought out when the patient is asked to look round—the eyes only are moved, or the whole body is rotated. Bearing the possibility of this condition in mind there is not much difficulty in diagnosis, but in doubtful cases a skiagram should be taken (Fig. 619).

Fig. 619. Skiagram of the cervical spine, taken laterally, showing tuberculous caries of the bodies of the 2nd and 4th cervical vertebrae. The site of the cervical caries is indicated by the arrow and bracket. (By Dr. W. H. Cobbell.)

New Growth in one of the cervical vertebrae may cause progressive stiff neck, and generally much local pain on movement: the diagnosis may suggest itself when the patient

Fig. 620. Skiagram of the cervical spine, taken laterally, showing sarcoma of the body of the 5th cervical vertebra, the growth extending upwards to destroy part of the body of the 4th, and downwards to destroy part of the body of the 6th. (By Dr. C. Thurstan Holland).

is known to have had a new growth elsewhere, especially a carcinoma of the breast or of the thyroid gland: cases of primary new growth of the vertebrae are fortunately rare, but myeloid sarcoma does occur (Fig. 620): it can generally be diagnosed only after the patient has been observed for a long time. The symptoms simulate those of caries.

Infective Arthritis of the Cervical Vertebrae.

Following infective diseases such as scarlet fever, typhoid fever, paratyphoid fever, diphtheria, and tonsillitis, especially in children, there may ensue a very chronic form of infective arthritis affecting one or several of the cervical vertebrae, and going on sometimes to complete bony ankylosis. Similar stiffness of the back of the neck, especially its lower part, with pain on movement, is apt to occur in sufferers from rheumatoid arthritis (p. 426): it is due to infective peri-arthritis of the vertebral joints, secondary to toxic absorption from such sources of chronic infection as pyorrhea alveolaris or uncured gonorrhoea.

Spondylitis Deformans (Figs. 621, 622) causes fixation of the neck, though the movements of nodding 'yes' and 'no' remain: the nature of the case is at once indicated, however, by the fixation of the other regions of the spinal column also 'poker-back'.

Fig. 621. Spondylitis deformans, 'poker-back'. The patient was unable to raise the head, though he could just nod and shake it slightly. Except for the atlas and axis, the whole vertebral column was fixed. There was no affection of other joints in the body, and the general health was good.

Fig. 622. Another case of spondylitis deformans, kyphosis with some scoliosis of the dorsal region. There was no generalized arthritis, but the whole vertebral column except the atlas and axis was fixed as the result of the spondylitic changes. The lumbar region is unduly hollow; the dorsal region unduly convex backwards.

Injuries to the Neck. A stiff neck may arise from some slight injury, such as a blow or a sudden twist. This will be clear from the history. Severe injuries involving fracture

or dislocation are almost always fatal: if not immediately, then in a few days. A rare injury that may not be fatal is unilateral dislocation of one of the cervical vertebrae. This may result from a fall on to the head. From the start there are great pain and stiffness in the neck, the head being fixed immovably and turned to the opposite side to that of the displacement.

Burns. A self-evident cause of stiffness is the cicatricial contraction following a burn on the neck.

Stiffness and retraction of the head are important indications of *meningitis*, but they are by no means constant: when present they are generally accompanied by other well-marked signs of meningitis.

Stiffness of the neck is one of the earliest signs of *tetanus*: it is rarely the only one, however. The trouble soon spreads to the jaw, causing trismus and other characteristic symptoms (p. 885).

George E. Gask.

STOMACH, DILATATION OF. (See DILATATION OF THE STOMACH, p. 218.)

STRABISMUS. Squints may be classified according to their *direction*, into convergent, divergent, or altitudinal: according to their *cause*, into paralytic and non-paralytic (concomitant). The diagnosis between paralytic and non-paralytic strabismus is, as a rule, easy. In a paralytic strabismus the convergence or divergence of the two eyes is not constant in amount in all directions, as the farther the eyes are moved over in the direction of the action of the paralysed muscle the greater will be the deviation from parallelism. In a concomitant squint the eyes always bear the same relative position to each other in whatever direction they are turned.

The diagnosis of the cause of a paralytic strabismus, which is associated with *DIPLOPIA*, is discussed under that heading (p. 220). The causes of concomitant strabismus are usually

Error of refraction: Failure of binocular vision: Defective vision in one eye: or the association of one or more of these conditions. The cause cannot be determined accurately without a careful examination of the ocular refraction under a mydriatic. In general terms it may be stated that convergent squints of this type are, as a rule, due to hypermetropia, and divergent squints to myopia.

Herbert L. Eason.

STRANGURY differs somewhat from mere pain on micturition, in that, in addition to severe pain before, during, or after the act, the patient is troubled constantly by urgent and repeated necessity to discharge his urine, sometimes as often as every few minutes, yet without any satisfactory relief to his discomfort. The condition is also spoken of as vesical tenismus. Very little urine is passed each time: sometimes the desire and the necessity are urgent when there is no urine in the bladder at all. The causes resolve themselves into five groups, as follows:

1. Nervous Conditions, especially:

Hysteria	Irritable bladder	Tabes dorsalis
Neurasthenia		(vesical crises).

2. Obstruction to the Urine Outflow, leading to Retention with Overflow:

Urethral stricture	Extreme prolapse of the uterus and bladder
Enlarged prostate	Calculus impacted in the urethra
Prostatic calculus	Inflamed urethral caruncle
Carcinoma of the prostate	Gonorrhœa
Retroverted gravid uterus	Urethritis other than gonococcal
Uterine fibroid	Periprostatic abscess
Ovarian cyst	Periproctal abscess.
Ovarian carcinoma	
Impacted in the pelvis	

3. Local Affections of the Bladder Wall:

Injury	Tuberculous cystitis	Infiltration by
Acute cystitis	Papilloma vesicæ	Carcinoma of the uterus
Chronic cystitis	Carcinoma vesicæ	Carcinoma of the rectum
Calculus irritating the trigone		Acute vesiculitis.

4. **Reflex Conditions** :--

Inflamed hemorrhoids	Coli bacilluria	} Even before there is infection of the bladder wall.
Injury to the back	Pyelitis	
Tuberculous kidney, before the bladder is involved		

5. **The effects of certain Drugs, especially** :--

Cantharides	Urotropine or hexamethylene-	Helmitol
Oxalic acid	tetramine	Cystopurin
Turpentine		

Most of the conditions mentioned above, and the methods of distinguishing between them, are discussed in the article on MICTURITION, ABNORMALITIES OF (p. 490). Irritable bladder is discussed under the heading of OXALURIA (p. 523). Two points of importance deserve stress, however, and chief amongst these are the vesical crises of *tabes dorsalis*. The patient's sole complaint may be that he can never be far from a lavatory because of acute and painful calls to empty his bladder at frequent intervals: sometimes he has no sooner passed what is in his bladder than he has to run back and do it again, though there is no urine whatever to pass; and his vesical pains may be extreme. From loss of sleep his general health suffers, and he becomes anæmic and wasted to such an extent that carcinoma of the bladder or genito-urinary tuberculosis are simulated, or acute cystitis may be diagnosed erroneously. The true diagnosis will be suggested when it is discovered that the knee-jerks are absent and the pupils give the Argyll Robertson reaction: in some cases, however, the nature of the malady may be difficult to decide for a time, because crises of all kinds, like the lightning pains, are apt to develop in the earlier stages of *tabes* when the knee-jerks may as yet not be absent. Both jerks should be tested, for there are cases in which one knee-jerk is still present when the other has disappeared. A thorough examination of the urine and bladder should be carried out even if the patient is known to have *tabes dorsalis*, for he may have a gross lesion of the bladder in addition to his nerve disease. The actual cystitis resulting from retention of urine with overflow is generally a late symptom, and not a relatively early one like the vesical crises, which are quite distinct phenomena. As time goes on the bladder crises may cease spontaneously, just as the lightning pains, the rectal crises, and the other painful phenomena of *tabes* are apt to do.

The other point that merits attention is the strangury that certain drugs produce. *Cantharides* is familiar in this respect, but more from its prominence in text-books upon forensic medicine than from its occurrence in actual practice. The same applies to *oxalic acid* and to *turpentine*. It is less recognized that certain drugs in common use may be responsible for very similar symptoms, in which respect *helmitol*, *cystopurin*, and *methylenetetramine* are important. These are all employed in the treatment of pyuria,

well as for gall-stones and other conditions. If given for pyuria, when there may have been frequent and painful micturition already, the increased frequency and pain that sometimes ensue when any of the above drugs are administered are apt to be attributed to an increase in the cystitis or other genito-urinary lesion, and the dose of the drug is increased instead of diminished. It may be only after the patient deliberately ceases to take the medicine that the fact of the increase in the symptom being due to the drug becomes obvious; some cases develop strangury every time they take urotropine, and lose the symptoms a day or two after they have stopped the medicine. In some instances transient hæmaturia accompanies the strangury, and the danger always is lest these symptoms be attributed to the disease and not to the drug.

Speaking generally, it is in cases in which the urine is concentrated, or at least in small amount, that urotropine and its allies are most liable to cause strangury and hæmaturia. If the patient drinks abundance of water, so as to dilute his urine, these symptoms often disappear. Sometimes the patient can take helmitol with ease when he cannot bear urotropine, and vice versa. The important point is that urotropine and other drugs of like nature may be responsible for such strangury as may simulate local disease of the bladder, and unless this is borne in mind an erroneous diagnosis is liable to be made.

Herbert French.

STRIDOR is a term used to denote a harsh, vibrating noise produced as the air passes in or out of a partially obstructed larynx or trachea. It may be due to many different causes, which may be classified as follows :

1. Partial Obstruction Inside the Larynx or Trachea :

Mucus or mucopus
Foreign body

Caseous gland bulging or rupturing into the trachea.

2. Affections of the Wall of the Larynx or Trachea :

Diphtheria
Acute oedema due to
Bright's disease
Potassium iodide
Irritant vapours such as ammonia or chlorine
Acute laryngitis streptococcal, pneumococcal, staphylococcal

Secondary infection in cases of tuberculous, syphilitic, malignant, traumatic, or post-typhoidal ulceration
Stenosis after tracheotomy or cut throat
Epithelioma of a vocal cord
Fibroma of a vocal cord
Epithelioma of the trachea
Syphilitic stenosis.

3. Swellings Outside Compressing the Larynx or Trachea :

Enlargement of the thyroid gland
Enlargement of the thymus gland
Thoracic aneurysm
Mediastinal new growth
Postpharyngeal abscess

Epithelioma of the œsophagus invading the trachea
Malignant glands in the neck
Cellulitis of the neck
Erysipelas of the throat
Angina Ludovici.

4. Bilateral Abductor Paralysis of the Vocal Cords, generally due to syphilitic degeneration of the vagal-nuclear nerve-cells : though occasionally the result of bilateral injury to the recurrent laryngeal nerves after the operation of thyroidectomy.

5. Unilateral Vocal Cord Paralysis in a few cases : generally if one cord remains normal there is no stridor. The diagnosis of the causes is given on p. 606.

6. Spasmophilia, or undue tendency to spasmodic muscular contractions, such as is seen in rickets (*laryngismus stridulus*), and in tetany—(a) carpopedal of infants, (b) in adults after parturition, after thyroidectomy, in association with gastro-intestinal lesions, notably pyloric stenosis, gastric ulcer, duodenal ulcer, and gastrectasis.

7. Hysteria.

Distinction is sometimes drawn between inspiratory and expiratory stridor, and stridor which is both inspiratory and expiratory : but in practice such a distinction is not helpful. The main value of stridor as a symptom is that it indicates stenosis of the main air-passages by one or other of the above causes, except when it is functional : *hysterical stridor* ceases during sleep, is nearly always confined to the female sex, as a rule between the ages of fifteen and thirty, and is often associated with other functional nervous symptoms, such as globus hystericus and functional aphonia (p. 606). *Laryngismus stridulus* may be suggested by the age of the patient : by the other signs of rickets that are present : and by the fact, perhaps, that the child has had precisely similar symptoms on previous occasions. It is most important, however, not to diagnose spasmophilia and *laryngismus stridulus* until proper examination has been made to exclude foreign body, laryngeal diphtheria, and postpharyngeal abscess, or life may be lost. Stridor should never be diagnosed as functional until every possible organic cause has been excluded. The differential diagnosis of the causes of obstruction to the main air-passages will be found discussed on page 246.

Herbert French.

STUPOR. (See COMA, p. 153.)

STUTTERING. (See SPEECH, ABNORMALITIES OF, p. 774.)

SUCCUSSION SOUNDS may be heard when a part that contains any considerable bulk of both fluid and gas is shaken whilst the ear or the stethoscope is applied over it. Sometimes the sounds are so loud that they can be heard at a considerable distance from the patient. A good example of succussion is often afforded by the normal stomach after

a quantity of fluid has just been swallowed. It is a mistake to suppose that gastric succussion sounds are evidence of abnormality: they merely prove that the viscus contains fluid and gas at the same time: the gas may be due to fermentation, but it is often nothing but air that has been swallowed during drinking. The chief value of gastric succussion sounds is that, according to the position in the abdomen at which they can be heard, they afford some clue as to the position, and perhaps as to the size, of the stomach. They should not be heard lower than the umbilicus when the patient is recumbent: if they are, the stomach is either displaced downwards, or dilated, or both.

Another variety of succussion sounds may sometimes be heard in the chest, especially in cases of *hydropneumothorax*: when the patient deliberately oscillates his trunk to and fro, and then stops, the fluid and air can be heard making noises like those produced when a partly-filled barrel is moved about. Sometimes the fluid splashes up on to the collapsed lung and then drips off again into the pool at the bottom of the pleural cavity, each drop echoing in the cavity and producing a metallic clink like a *bruit d'airain* or coin sound. Similar succussion sounds may be produced by a *pyopneumothorax* or a *hæmopneumothorax*, the difference between these being decided, as a rule, by exploratory needling.

Succussion sounds other than those due to the stomach, or to gas and fluid in the pleural cavity, are uncommon, but the following is a list of the chief possible causes:

1. Causes of Succussion Sounds in the Thorax:

Hydropneumothorax	with the <i>Bacillus coli communis</i> , and
Pyopneumothorax	containing gas and pus
Hæmopneumothorax	Hydropneumopericardium
Diaphragmatic hernia	Pyopneumopericardium
Subdiaphragmatic abscess communicating with stomach or duodenum, and so containing air and pus: or else infected	A huge phthisical cavity beneath a thin chest wall.

2. Causes of Succussion Sounds in the Abdomen:

The normal stomach	<i>coli communis</i> , either in a local abscess
Dilatation of the stomach	(e.g. appendicular or subdiaphragmatic)
Enormous dilatation of the cæcum	or in the general peritoneum
Enormous dilatation of the sigmoid colon	Subdiaphragmatic abscess communicating with the interior of the stomach
Enormous dilatation of some other part of the colon	Air and urine in the bladder (see <i>PNEUMATURIA</i> , p. 646)
Pneumoperitoneum, due to: (a) Perforated gastric ulcer: (b) Perforated duodenal ulcer: (c) Perforated typhoid ulcer of the intestine: (d) Perforated tuberculous ulcer of the intestine: (e) Perforated malignant ulcer of the colon: (f) Production of gas by the <i>Bacillus</i>	Gas-production by the <i>Bacillus coli communis</i> or other germs in a large pyonephrosis
	Infection of an ovarian cyst or other collection of fluid by a gas-producing micro-organism.

Succussion Sounds in the Chest. The diagnosis is not as a rule difficult. It is very rare indeed for a *phthisical cavity* to give succussion sounds: but should it do so, the phenomenon would be apical rather than basal, and thus distinguishable from most cases of hydro- or pyo-pneumothorax. It is possible for the latter to be apical, however, if old adhesions prevent the parietal and visceral layers of pleura from separating in the lower part of the chest, and then, if tubercle bacilli were found in the sputum, it would become a matter of opinion as to whether the sounds were produced in the pleural cavity or in a huge *comica*. *Hydro-* and *pyo-pneumopericardium* are very rare, and they are at once distinguished by the extraordinary churning sounds made by the heart beating within the mixture of air and fluid. Survival is improbable. The cause is generally an epithelioma of the œsophagus opening the pericardium from behind, a foreign body such as a tooth-plate ulcerating through from the œsophagus, the opening of an air-containing subdiaphragmatic abscess through the diaphragm into the pericardium, or infection of the pericardial sac by a gas-producing organism such as the *Bacillus coli communis*.

A *subdiaphragmatic abscess* containing air owing to communication with a hole in a gastric or duodenal ulcer sometimes pushes the diaphragm up so high that the condition may be mistaken for hydro- or pyo-pneumothorax: it may be possible to distinguish the two by knowing that the trouble began with gastric ulceration: on the other hand, it may be impossible to tell which it is until the position of the diaphragm is ascertained, either

by the use of the X rays (*Fig. 623*) or by operation. When the trouble is sub-diaphragmatic the tendency is to displace the heart upwards rather than towards the opposite side of the chest (see p. 376), whereas the contrary is true in the case of pneumothorax.

Diaphragmatic hernia is very rare; it may be congenital, or it may be the result of severe injury to the abdomen and chest. In neither case are the patient's prospects of survival good. The exact diagnosis may not be arrived at without operation or post-mortem examination; if the stomach is herniated into the thorax, however, the effect of eating and drinking upon the physical signs may point to the diagnosis, or the X rays may be used to demonstrate the gastric shadow after the administration of bismuth or barium salts by the mouth (see *Fig. 514*, p. 649).

In most cases of *hydropneumothorax* there is little difficulty as to the diagnosis of the condition itself; it may be less easy to decide what the hydropneumothorax is due to. If the onset has been sudden with acute pain in the affected side of the chest, cyanosis, and dyspnoea, the commonest cause is *phthisis*. The sputum should be examined for tubercle bacilli. In some instances an injury may have been the immediate cause, but injury seldom produces hydropneumothorax unless there was already a tuberculous or other lesion in the lung at the time of the accident. Hydropneumothorax may result temporarily after *paracentesis thoracis*. If there has been bleeding at the same time, *hæmopneumothorax* may be found, and it is common after bullet wounds of the chest. Either a hydro- or a hæmo-pneumothorax may become infected with pyogenic organisms and converted into a *pyopneumothorax*. The diagnosis will be confirmed by needling the chest. Pyopneumothorax is apt to escape detection, however, because it may arise when the patient is too ill to be shaken in cases of gangrene of the lung for instance, resulting perhaps from lobar pneumonia, obstruction of a bronchus by a foreign body or a new growth, the breaking down of an infective bronchopneumonia or pulmonary infarct, or the conversion of a pleural hæmatoma into a mixture of pus and gas as the result of infection by gas-gangrene organisms after gunshot or other wound of the chest. Generally speaking one may say that the existence of well-marked succussion sounds in the pleural cavity of a patient who has sufficient vigour to shake his own body to and fro indicates hydro-pneumothorax of phthisical origin.

Fig. 623. Skiagram of a gas-containing sub-diaphragmatic abscess pushing up the right cupola of the diaphragm. (By Dr. C. Thurston Holland.)

Succussion Sounds in the Abdomen.—The first point in the differential diagnosis of succussion sounds in the abdomen is to decide whether the sounds are *gastric* or not. Generally this is obvious; if there is doubt, the effect of putting more gas or more fluid into the stomach by taking a seidlitz powder in two halves, or by drinking a quantity of water, will usually so change the character and distribution of the sounds if they are gastric that little doubt will remain; or the X rays and bismuth method of demarcating the stomach may be employed. The existence of gastric succussion is no proof of gastrectasis; if, however, the succussion sounds are audible over a larger area than the normal stomach should occupy they afford valuable evidence of *gastrectasis*, and the next step will be to determine the cause of the latter. Dilatation of the stomach has three main causes, namely, atony, non-malignant pyloric or duodenal obstruction, especially by a healed simple ulcer, and malignant pyloric obstruction by primary gastric carcinoma.

The presence of visible peristaltic waves, or the occurrence of vomiting, will exclude simple atony, which can never be diagnosed with certainty until it is known that there is no pyloric obstruction. The latter may be indicated by periodic vomiting; by the

abundance of the fluid vomited being greater than the amount taken at the last meal ; by the presence in it of particles of food eaten a day or more previously—ham, for instance, vomited on Tuesday when last partaken of on Sunday ; by the visible peristaltic waves corresponding with the stomach ; and by the presence of sarcinae in the vomit (see *Fig.* 258, p. 302). The most certain method of detecting pyloric stenosis, however, is by means of bismuth or barium and the X rays, especially in those cases, not infrequent, in which vomiting does not take place in spite of great gastrectasis : one needs to know not merely that the stomach is big (*Fig.* 185, p. 219), but that it still contains residual bismuth at the end of eight hours (*Fig.* 186), long previous to which it should have discharged all its bismuth contents if it were normal.

It is often a matter of extreme difficulty to decide whether pyloric stenosis is simple or malignant, though upon the whole the shorter the history, the older the patient, and the more definite the pyloric thickening or lump, the more likely is the lesion to be carcinomatous. The latter may occur in quite young subjects, however, even between 20 and 30 ; and a long history does not exclude carcinoma, since some cases of simple ulcer ultimately become malignant. Even when laparotomy is performed for the relief of the condition the precise nature of the ulcer may be quite doubtful : sometimes, indeed, post-mortem examination fails to decide whether the stenosed pylorus was carcinomatous or not, until microscopical examinations have been made. It has been stated that if the gastric juice after a test meal contains a normal amount of HCl, the diagnosis is unlikely to be carcinoma, and vice versa ; but even this general rule has many exceptions (p. 344).

The diagnosis of pyloric stenosis due to other causes than adhesions, a healed ulcer, or a carcinoma is seldom possible without a laparotomy : occasionally such out-of-the-way things as a calcified retroperitoneal cyst adherent to the pylorus and thought to have been a carcinoma pylori may be found.

If there are well-marked abdominal succussion sounds that can be shown to be definitely not gastric there are generally other well-marked signs and symptoms which materially assist the diagnosis.

Succussion sounds in the general peritoneal cavity are excessively rare, for even though this cavity should contain both gas and fluid, for instance after perforation of a typhoid ulcer, the coils of bowel prevent the sounds from being produced readily. The list of causes given above indicates the conditions that may be present. It would clearly be next to impossible to diagnose most of them unless the previous state of the patient were known accurately, or unless exploratory laparotomy were resorted to. It is important to remember that the *Bacillus coli communis* produces gas, so that intra-abdominal abscesses, appendicular and otherwise, are occasionally resonant. The occurrence, however, of marked non-gastric succussion sounds in the abdomen of a patient who is not acutely ill will generally arouse a suspicion that there is distention with gas and fluid of some part of the large bowel, especially the caecum or the sigmoid colon. This distention will generally be the result either of chronic constipation or of some cause of intestinal stenosis.

In cases of idiopathic dilatation of the colon, volvulus of the sigmoid colon, or Hirschsprung's disease, the sigmoid dilatation may be so extreme that this part of the intestine bulges up as far as the diaphragm (*Fig.* 145, p. 164, and *Fig.* 385, p. 486) ; succussion sounds in such a dilated colon might lead to the erroneous diagnosis of gastrectasis, but it is not common to get succussion because the distended colon contains faecal material that is not sufficiently liquid : the pear-shaped outline of the dilated viscus, and the history of most troublesome constipation for years, may indicate the nature of the case, but sometimes the fact that succussion sounds are colonic and not gastric can be determined only by giving bismuth by the mouth and then outlining the stomach by the dark shadow cast by the bismuth under the X rays, or alternatively, by X-raying the colon after a bismuth enema.

SUGAR IN THE URINE.—(See GLYCOSURIA, p. 326.)

SUPPRESSION OF THE MENSES. (See AMENORRHOEA, p. 22.)

SUPPRESSION OF THE URINE.—(See ANURIA, p. 54.)

SWEATING, ABNORMALITIES OF. The functional disorders of the sweat-glands, *sudamen (miliaria)* and *hidrocystoma*, are dealt with from the diagnostic point of view in the article on VESICLES (p. 913). The other abnormalities require but the briefest notice, for it is hardly possible to confuse them with each other or with any other conditions. In *hyperhidrosis* the secretion of sweat is excessive either over the whole skin or in some particular region, e.g., the palms and soles, and especially covered parts furnished with large sweat-glands, such as the axillæ and genital regions. Occasionally hyperhidrosis is limited to the area of distribution of a particular nerve—the fifth, for example. In some cases a peculiar pink tint of the inner side of the palm and the ball of the little finger and thumb has been noticed. In rare instances hyperhidrosis in delicate children is associated with *granulosis rubra nasi*, a condition in which the skin of the nose becomes intensely red, and is dotted over with minute deep-red specks and papules, the papules gradually developing into pustules which soon dry up. The cells around the sweat-ducts are infiltrated, and both ducts and coils, and also the blood-vessels and the lymphatic spaces of the corium, are dilated. This complication is distinguishable from rosacea by the age of the patient, the absence of telangiectases and of change in the sebaceous glands; from eczema, by the absence of vesiculation and weeping, and its obduracy to local treatment; from lupus erythematosus, by the absence of scales; and from lupus vulgaris, by the absence of apple-jelly nodules. The night sweats of *phthisis*, and those associated with *rickets* and with *infantile scurvy* (Barlow's disease, p. 679), are not, as a rule, difficult to attribute to their cause.

In *anidrosis* the secretion may be merely diminished or totally suppressed, and either the whole skin, or only some particular area, may be affected. The abnormality is usually associated with ichthyosis, psoriasis, eczema, sclerodermia, belladonna poisoning, with malnutrition or with disordered innervation; under the latter heading one may mention in particular the unilateral sweating of the face and head that accompanies irritation of the cervical sympathetic by an aneurysm, thoracic cyst, or new growth; the outbursts of local perspirations, such as a band of sweating round the body, that constitute a rare symptom of *tubes dorsalis*—a sweating crisis; and the sweating of half the body—*hemidrosis*—that may be a purely functional or hysterical phenomenon.

Bromidrosis, or foul-smelling sweat, sometimes associated with hyperhidrosis, may occur in connection with such general affections as acute rheumatism, uræmia, and scurvy, or following a serious illness like pneumonia. Occasionally generalized, it is much more frequently limited to particular parts, such as the feet, the axillæ, and the perineum. The foul smell is due to the growth of the *Bacillus fetidus* upon the sweat after exudation.

In *chromidrosis* both sweat and sebum may be coloured, generally some shade of blue, but occasionally red, green, yellow, violet, and even black. The pigmentation is usually localized, the most frequent situations being the eyelids, cheeks, forehead, and side of the nose; but occasionally the whole of the face and large parts of the trunk and limbs, and especially the axillæ and groins, are affected. The condition is often a neurosis, but it may be due to the ingestion of copper (green sweat), or of iron (blue sweat), or to the action of cocci or the *Bacillus pyocyaneus* upon the sweat after secretion. The chief point in diagnosis is the exclusion of imposture.

Hæmatidrosis, or bloody sweat, generally limited to particular parts, the face, hands, feet, navel, etc., may be a form of so-called vicarious menstruation, or an expression of emotional stress in highly-strung persons; it is sometimes simulated by the presence in the sweat of bacteria producing a red pigment, such as the *Bacillus prodigiosus*. *Uridrosis*, in which urinary constituents are present in the sweat in abnormal quantity, is not an idiopathic affection, but an accompaniment of such grave conditions as cholera and uræmia. It is quite unmistakable; the sweat has a urinous odour, white crystals will be seen on the skin, and the exudate gives an effervescing reaction with sodium hypobromite.

It is worthy of note that the sweat may have peculiar effects when the patient is taking certain drugs: for example, persons whose occupation it is to make polished steel implements may be discharged from their employment if they are taking mercury and iodide of potassium, because the articles they have polished go dull and spotty almost at once, in a way which does not result from ordinary perspiration.

Ernest Dore.

SWELLING, ABDOMINAL. This may be acute or chronic, general or local, and caused by abdominal accumulations that are mainly either gaseous, fluid, or solid. The *position, physical consistency, and duration* of abdominal swellings are their three outstanding clinical features for purposes of diagnosis. They may be classified as follows:

I.—Swellings in the Abdominal Wall.

II.—General Abdominal Swellings :—

A. Mainly Gaseous : Surgical emphysema ; Meteorism.

B. Mainly Fluid : Ascites ; Large cystic tumours ; Distention of hollow viscera ; Hydatid disease.

C. Mainly Solid : Obesity ; Constipation ; Inflammatory deposits ; New growths.

III.—Local Intra-abdominal Swellings :—

A. Due to General Causes : Encysted ascites ; Tuberculous peritonitis ; Hydatid disease ; Subphrenic abscess ; Phantom tumours ; Enteroptosis.

B. Due to Enlargement of Particular Organs.

I. SWELLINGS IN THE ABDOMINAL WALL.

Swellings situated in the abdominal wall itself can be recognized by their superficial position ; by their adherence to the skin, muscles, or fascia ; or by their not following the movements of the viscera immediately underlying the wall of the abdomen, to which they must therefore be superficial. But it may be impossible to distinguish between a fatty tumour in the deeper part of the wall, for example, and a fatty omental mass that has become adherent to the parietal peritoneum and so has practically incorporated itself with the abdominal wall.

Inflammatory swelling of the wall may occur by infection from without or, less often, from within. Thus a liver abscess may cause extensive redness and swelling in the right hypochondriac region ; infiltration of the abdominal wall is often met with in operations for appendicular abscess ; in acute cases of *Hodgkin's disease* and *lymphosarcoma*, tumours suggesting a subacute inflammatory process may occur in the abdominal wall, but they are really localized lymphadenomatous or sarcomatous deposits, not due to infection, and are associated with gland enlargement in other parts of the body. *Inflammatory swelling about the umbilicus* is not rare in newly-born infants, due to the entrance of infection by way of the cord ; in stout uncleanly adults the umbilical fossa may be the seat of intertrigo which becomes painful, swells, and suppurates ; but a far more serious umbilical inflammation may occur in patients, usually children, with *tuberculous peritonitis* ; a tuberculous mass in connection with the round ligament may break down, perforate at the umbilicus, set up a chronic discharge there, and ultimately establish a fecal umbilical fistula ; in rare cases

subdiaphragmatic or *perigastric abscess* may cause inflammatory thickening of the round ligament and umbilicus ; and after *pneumococcal peritonitis* of a degree that has not been sufficiently acute to call for urgent laparotomy, spontaneous purulent discharge from the umbilical region is not uncommon.

Œdema of the abdominal wall may be either local or general (see ŒDEMA, p. 511).

Tumours of the abdominal wall, excluding those due to inflammation, are rare except in certain situations. *Lipomata* and *fibrolipomata* may occur in any part of it, and in the inguinal or femoral rings closely imitate omental hernias ; diffuse symmetrical lipomatosis above and below the umbilicus and on either side of it may be a marked feature of *Dercum's disease* or *adiposis dolorosa*. *Herniæ* are common, particularly at the umbilicus and in the groins ; there is little likelihood that a definite hernial protrusion in any part of the abdominal wall will be overlooked, but minute hernias into the abdominal wall, such as may occur along the linea alba, especially above the umbilicus, at the femoral or inguinal rings, or along the linear semilunares, may suffice to produce complete intestinal obstruction and yet be small enough to demand very careful palpation for their discovery.

In *malignant disease* of the stomach, or in the region of the portal fissure generally, small secondary nodules may appear quite early at the umbilicus or in the round ligament just above it or in the urachus below it ; and this may occur before the primary tumour has given rise to any definite signs or symptoms.

II. GENERAL ABDOMINAL SWELLINGS.

A. Mainly Gaseous. In certain cases of extensive *surgical emphysema* the fascial planes of the abdominal wall are invaded and dissected out by gas, which imparts to them a highly characteristic crepitant crackling feeling on palpation. The gas may have entered from wounds in the neck, thorax, or trachea, or it may have been generated by gas-producing microbes in any abscess or focus of inflammation in the trunk or viscera or from gas-gangrene, and have made its way thence into the abdominal wall.

Distention of the intestines with gas is an event so common as to be familiar to all; its diagnosis is discussed under METEORISM (p. 485). In this condition the whole of the abdomen, or in special cases some part of it only, is distended, and on percussion gives a highly resonant or tympanitic note. It often happens that the outlines of the gas-distended viscera can be seen on the abdominal wall, particularly when it is looked at in an oblique illumination. The increased size of the inflated intestine is apt to produce displacement of the other viscera; the dome of the diaphragm is pushed up into the chest, carrying the heart with it and shifting the apex-beat upwards; the liver is similarly pushed up, and in addition it is often caused to rotate round a transverse axis, its lower anterior edge ascending and its lower posterior edge descending, with the result that the area of liver dullness in front is much reduced, or even lost altogether; but it is reduced only a little in the mid-axillary line so long as the gas remains in the intestine; and if the liver dullness in the mid-axillary line disappears, the diagnosis of free gas in the peritoneal cavity is to be made.

B. Mainly Fluid. The diagnosis of the various causes producing accumulations of fluid in the peritoneal cavity is given under the heading ASCITES (p. 59).

C. Mainly Solid. In OBESITY (p. 505) the abdomen may swell either in consequence of the deposit of fat in the abdominal wall itself, or as the result of fatty deposits behind the peritoneum generally, in the mesentery, the omentum, and the appendices epiploice. In very fat patients it is rarely possible to diagnose the exact nature of an intra-abdominal mass by the usual methods of palpation and percussion, and without having recourse to exploratory laparotomy, because the abdominal walls are so thick. The frequency with which inconveniently large fatty accumulations occur in the abdomens of such persons must not be forgotten when the diagnosis of some vaguely-felt tumour within the abdomen has to be considered.

In severe chronic cases of CONSTIPATION (p. 158), abdominal distention may result from accumulation of feces in the large intestine, particularly when dilatation of the colon, idiopathic or secondary, is present. The scybala can usually be felt, perhaps soft and plastic in the region of the ascending colon, usually hard and nodular in the descending and sigmoid colon. *Idiopathic dilatation of the colon (Hirschsprung's disease)* seems to be congenital, and is associated with much hypertrophy of the colon (Fig. 385, p. 486). A description of it will be found on p. 163. In older patients a very similar *dilatation and hypertrophy of the colon* may come on as the result of chronic obstruction about the lower end of the large intestine. As much as 47 lb. of feces may accumulate in the intestines of such patients.

In rare cases of chronic, particularly tuberculous, peritonitis, semi-solid *inflammatory masses* may bring about a general swelling of the abdomen; the diagnosis is discussed under ASCITES (p. 63 et seq.). General swelling of the abdomen may occur in *malignant disease* of the peritoneum, due in part to the growth of numerous secondary malignant nodules, in part to a concomitant ascites. The symptoms are often vague at first—loss of weight, strength, appetite, with indefinite abdominal disorders. The abdomen enlarges, and if there is not much ascites the secondary deposits can be felt obscurely through the abdominal wall. Occasionally they can be palpated in the abdominal wall itself near the umbilicus, or in the urachus below it. Emaciation becomes marked; the skin loses its elasticity and often develops a diffuse, brownish pigmentation; bedsores are not rare. If a primary growth can be made out in any of the thoracic, abdominal, or pelvic organs, or in the mamma or testis, the diagnosis will not be difficult, especially if enlarged glands are found in the groins or axilla, if the ascitic fluid is hæmorrhagic, and if it contains multinuclear endothelial cells, or cells with atypical mitotic figures.

III. LOCAL INTRA-ABDOMINAL SWELLINGS.

A. Due to General Causes. Causes which ordinarily produce general swelling of the abdomen sometimes give rise to only local swelling. Thus in *encysted ascites*, left after acute diffuse peritonitis, or accompanying chronic peritonitis, an accumulation of fluid bounded by adhesions between the adjacent viscera may be found in any part of the peritoneal cavity, but most often in the flanks or the pelvis. If a good history can be obtained the nature of such a cyst may suggest itself; though the diagnosis may be obscure until laparotomy has been performed.

Abdominal swellings of the most various size and position may occur in *tuberculous peritonitis*. Many are composed of infiltrated omentum, others of enlarged tuberculous mesenteric glands, others of doughy masses of adherent intestine. The amount of ascitic fluid varies widely in different cases. When there is much, and the patient is an adult, the diagnosis of cirrhosis of the liver may be made; when the peritonitis is dry (the obliterative form), the abdominal cavity may be occupied by a doughy, tender mass that presents areas of alternating resonance and dullness. As a rule the patient is thin, anæmic, definitely ill, with a drawn facial aspect; abdominal pain and tenderness are usual, nausea and constipation are frequent; in acute cases there is fever, in chronic the temperature is not high, but irregular, or may even be subnormal. If

Fig. 623a. Scolices of *Tania echinococcus* in fluid from a hydatid cyst. In some the hooklets are seen as a ring on the free extremity; in others the ring is invaginated. ($\times 30$.)

there is ulceration of the large intestine diarrhoea may occur, and blood may be passed in the motions. Discovery of tuberculosis in some other part of the body is argument for regarding a case with such signs as tuberculous. A general or patchy brown pigmentation of the skin is not uncommon.

Single or multiple *hydatid cysts* may occur in any part of the abdominal cavity. Usually they are single. Most occur in the liver; more rarely they affect the spleen, omentum, mesentery, or perium. The cyst grows slowly, and is spherical except in so far as it is moulded by the pressure of adjacent structures. It contains a clear saline fluid in which may be found hooklets (Fig. 76, p. 65), scolices (Figs. 623a, 623b), and secondary or daughter cysts detached from the walls of the parent cyst. Unless large enough to cause mechanical pressure symptoms, the single hydatid cyst gives rise to little pain or complaint. It may produce bulging of the overlying abdominal wall, smooth, rounded, more or less tense, dull on percussion; if of a certain degree of tenseness it may yield the hydatid thrill just as any other cyst may. Hydatid cysts in the mesentery, omentum, or peritoneum are often multiple, and may be felt as rounded tumours accompanied by ascites; the disease runs a slower course than malignant peritonitis, and echinococcal cysts may be found in the ascitic fluid if it is tapped. As a rule they are secondary to a primary cyst in the liver. They cause a slowly progressive enlargement of the abdomen, which appears to be filled with a solid or semi-solid mass; if the individual cysts are large they can be seen outlined on the abdominal surface, and can

Fig. 623b. A single scolice with ring of hooklets invaginated. ($\times 120$.)

(Figs. 623a and b from photographs by Sir William Lester, from a specimen belonging to Dr. Louis Werner, of Dublin.)

be felt. They are freely movable, and not connected with any particular viscus; they do not, as a rule, give the hydatid thrill on percussion. Peritoneal hydatid disease is rare except in countries (Iceland, Australia, or South America) where the inhabitants live in close company with dogs that are the hosts of *T. echinococcus*. Eosinophilia may be found, and when the cysts are living and active the patient's blood-serum may give a specific hydatid precipitin reaction, though the absence of these signs does not exclude the disease; exploratory laparotomy may be necessary before the diagnosis can be established.

Any part of the abdomen may swell from the formation of an *abscess*, several forms of which are more or less localized, and are considered below (p. 808); others present more generalized abdominal signs and symptoms, and will for that reason be considered here. A *subphrenic abscess* is any abscess in contact with the under surface of the diaphragm except those situated in the liver or in the spleen. It is intraperitoneal in more than half the instances: it contains gas in about half the cases. The *simple or non-gaseous abscesses* are generally the result of appendicitis or of suppuration in the liver, and so are usually on the right side of the body; less often they are secondary to gastric or duodenal ulcer, or to suppuration spreading from the pancreas, kidney, Fallopian tubes, spleen, or thorax. They are deep-seated, and tend to produce abdominal swelling with signs and symptoms that are indefinite. The onset is insidious, often consisting in nothing more than failure to recover from the primary disorder—appendicitis, hepatic abscess—after it has been treated surgically; the patient remains seriously ill, with fever and quick pulse, leucocytosis, and often a septic aspect. If the abscess is at the back the signs may point to pleurisy or pleural effusion, with the appropriate pain and friction sounds. If it pushes forwards, the hypochondrium and epigastrium may bulge in front and become tender. The diagnosis of subphrenic abscess may be very difficult when there is no obvious antecedent to suggest its occurrence, especially if the abscess is behind and below the liver, and is complicated by pleurisy or empyema. If it is above the liver, it may be very difficult to say whether the pus is inside the liver or outside it, or both; enlargement of the liver downwards is in favour of intrahepatic abscess. Examination with the X rays is often of great assistance; but often it is necessary to give the patient a general anæsthetic and insert a long exploring needle successively into the intercostal spaces (tenth to sixth) in the scapular and mid-axillary lines. It must be thrust in deeply. As viewed by the X rays the diaphragm is depressed by empyema or pleural effusion, elevated by subphrenic abscess, and immobilized by either.

The *gas-containing abscess* or *subphrenic pyopneumothorax* is commoner in females than in males, and is usually due to the perforation of a gastric, or less often a duodenal, ulcer, or to appendicitis; in rare instances it is secondary to an ulcer of the colon or even to a suppurating hydatid cyst. It is usually on the left side. When a gastric ulcer perforates the onset is generally sudden, with acute abdominal pain and collapse; but both the ulcer and its perforation may be latent, and nothing more than a history of chronic dyspepsia may be obtainable. The abdomen soon becomes distended; hectic fever, with rigors, rapid pulse, leucocytosis, and shortness of breath, are the symptoms likely to appear. The physical signs, on the whole, resemble those of PNEUMOTHORAX (p. 647); the diaphragm is pushed up into the thorax, and the gas in the abscess cavity below it causes the signs of pneumothorax to develop in the upper part of the abdominal cavity and the lower part of the thorax. The picture is complicated by the fact that the inflammatory process habitually spreads through the diaphragm, so that the signs due to pleurisy, with or without effusion, are added. The diagnosis has to be made between this condition and true pneumothorax. The points that serve to distinguish the two are, that in pneumothorax the gas seems to occupy the whole of one side of the thorax, the heart is pushed or pulled over to the sound side, and the physical signs are limited to the thorax; whereas in subphrenic pyopneumothorax the signs occur at the base of one or both lungs but not at the apex, the heart is displaced upwards but not to either side, and the upper part of the abdominal cavity is involved as well as the thorax. Examination with the X rays is of the greatest service, for it shows that the gas-containing cavity is below the diaphragm and not above it (*Fig. 623*, p. 801); the readiness with which the level of the fluid in the abscess changes as the patient alters his position can also be noted, and proves that the abscess cavity contains gas as well as fluid.

The abdomen is not infrequently the seat of *phantom tumours*. These are felt as fixed

and more or less rounded smooth swellings, either in or immediately underneath the abdominal wall; they are dull on percussion, and may be tender on palpation. They are caused by involuntary contractions of the muscles in the area in which they occur; they persist when the patient's attention is distracted, and also during sleep, but disappear under a general anæsthetic. Phantom tumours are commoner in women than in men, and in the neurotic than in the stolid. They often persist for long periods, but may vanish when the patient believes that they have been cured. A phantom tumour in the region of the liver may simulate cholecystitis, hepatic abscess, or gumma; in the left hypochondrium, gastric carcinoma; in the appendix region, an appendicular abscess; above the pubes, pregnancy (*pseudocyesis*).

Fig. 624.—The regions of the abdomen: for the significance of the numerals, see the table below.

In *enteroptosis* (Glénard's disease), or downward displacement of abdominal viscera, any or all of the organs may slip away from their normal position and attachments. (Fig. 146, p. 165). The diagnosis must be made by the discovery that one or more of the viscera is out of place, and is also abnormally mobile; it is confirmed by determining the position of the stomach and colon by X rays after a bismuth meal (Figs. 432, 433, p. 526).

B. The Regional Diagnosis of Local Abdominal Swellings.

For clinical purposes the abdomen may be subdivided into nine regions by two vertical lines drawn through the middle of Poupart's ligaments and by two horizontal lines, one passing through the lowest points of the tenth ribs (the subcostal line), the other drawn at the level of the highest points of the iliac crests (Fig. 624). The

viscera, or portions of viscera, commonly contained in the areas thus demarcated, are given in the table on page 808. The abdominal swellings that may be felt in and about these nine regions will now be considered seriatim, excluding the tumours situated in the abdominal wall itself that have been described on pp. 804, 805.

1. RIGHT HYPOCHONDRIAC REGION.

Most tumours in this area are connected with the liver or gall-bladder, and their diagnosis is discussed under LIVER, ENLARGEMENTS OF THE (p. 461), and GALL-BLADDER ENLARGEMENT (p. 314).

To regard the firm and rounded swelling produced by the upper segment of the right rectus abdominis muscle as evidence of tumour, enlargement, or induration of the liver or gall-bladder is a mistake easily and frequently made.

Tumours in connection with the *hepatic flexure of the colon*, excluding scybala, are rare. Scybala may be recognized by their general shape, by the ease with which they can be moulded or indented by the pressure of the fingers, and by their being dispersed by a purgative, or by adequate enemata. Carcinoma or tuberculosis of the colon may produce a palpable tumour here; and so may an intussusception. The diagnosis must rest upon the previous history and the course of the disease.

Tumours of the *kidney* or *suprarenal gland* rarely present themselves in this region of the abdomen.

2. EPIGASTRIC REGION.

Abnormal lobes in the liver, tumours in either of its lobes or in its falciform or round ligament, may be felt here.

In thin people and children the curvatures of the normal *stomach* when it is full may often be seen dimly outlined in the epigastrium, the lower curvature habitually, the upper less often; and the gastric succussion-splash can often be elicited here in healthy persons as well as in those with dilatation of the stomach. An epigastric splash is usually gastric, but may be colonic. In *dilatation of the stomach* due to obstruction at the pylorus (caused in infants by spasm or hypertrophy of the pylorus, in adults by malignant or cicatricial stenosis), waves of peristalsis travelling from left to right may be seen in the epigastrium. Similar waves, but travelling from right to left, occur in the colon of patients with obstruction in the rectum or sigmoid (see below). *Tumours of the stomach*, usually carcinomatous, rarely sarcomatous, or due to inflammatory deposits round a gastric ulcer, may sometimes be felt here, particularly when the patient takes a deep breath and drives the abdominal viscera down and out of the cover of the diaphragmatic dome: the normal pylorus can sometimes be felt in an infant, child, or thin adult, as a rounded finger-like mass deep in the right side of the epigastrium. The connection of a gastric tumour with the stomach can often be made out more clearly if that organ is inflated with gas; or by the method, little used in this country, of gastrodiaophany. Examination with the X rays after the administration of a bismuth or a barium meal is often of great assistance in obscure gastric cases, and should always be employed.

The *transverse colon* goes across the lower part of the epigastrium in some cases, more usually across the upper part of the umbilical area. Its sacculations and peristalsis are often outlined on the abdominal walls of pot-bellied rickety children or of thin adults, particularly when they are flatulent or constipated. In acute or chronic obstruction the peristalsis becomes much more marked. Tumours of the transverse colon are rare, except the common occurrence of scybala in it; carcinoma may produce a lump that may simulate gastric carcinoma until the case has been investigated with bismuth and the X rays, whilst a few cases of chronic hyperplastic tuberculosis of this part of the colon have been recorded, with great diffuse thickening of its wall and stenosis of its lumen.

Swellings in connection with the *omentum* lie below the colon and in immediate relation with the anterior abdominal wall, in front of the mass of small intestine. In *tuberculous peritonitis* it often forms an irregular rope or mass composed of inflammatory tissue, cheesy tubercle, or encysted exudate, that may lie in the epigastrium, or extend into any of the regions of the abdomen when the diagnosis of malignant disease of the intestine or some other viscus may possibly be made. Similar nodular enlargement and deformity of the omentum is common in *chronic peritonitis* of any sort; and it may become the seat of an

abscess in cases of perforated gastric ulcer. *Cysts of the omentum*, single or multiple, are not very rare, and are often inflammatory in origin. Tuberculous or inflammatory masses of omentum often adhere firmly to the anterior abdominal wall as well as to the neighbouring viscera.

Swellings derived from the *pancreas* push forwards from the depths of the abdominal cavity towards the epigastric and the upper part of the umbilical areas, and present themselves as deeply-seated vaguely-felt masses on palpation. They have the stomach, or the stomach and colon, in front of them, and are fixed to the posterior abdominal

Fig. 625. Acute pancreatitis. A, Hemorrhagic pancreas. B, Stomach. C, Gastro-colic omentum incised vertically. D, Lesser sac and blood-stained fluid therein. E, Area of fat necrosis.

(By kind permission of the 'British Journal of Surgery'.)

wall: they are usually made out best by examination under an anæsthetic: they move little on respiration, and often transmit from the adjacent aorta a non-expansile pulsation. They are separated from the liver and from the spleen by areas of resonance. These swellings may be carcinomatous, in which case wasting, anæmia, and jaundice are likely to be observed, with death in a few months' time; or due to chronic pancreatitis, when the course of the disease will be slower and there will be more epigastric tenderness and pain, with clayey stools and perhaps intermittent jaundice, a positive Cammidge's reaction (p. 128), or glycosuria. In acute pancreatitis the swollen pancreas has only exceptionally been palpated before laparotomy; the main symptoms are acute epigastric pain, vomiting, constipation, fever, and proneness to collapse, simulating in part acute intestinal obstruction and in part acute peritonitis, so that immediate laparotomy is usually resorted to

and the diagnosis established by the discovery of opaque yellow patches of acute fat necrosis in the omentum and elsewhere within the abdomen (*Fig. 625*).

Pancreatic cysts, so-called, are often cysts not in the pancreas but in its neighbourhood, and therefore better called peripancreatic cysts. *Pancreatic cysts* proper are single or multiple retention-cysts, usually the result of chronic pancreatitis; they form deeply-seated, smooth, rounded tumours, possibly giving a feeling of fluctuation. At first they occupy the lower epigastric or hypochondriac regions; but if they enlarge much they may fill the whole upper part of the abdomen, or extend down to the pubic symphysis or flanks. The symptoms of chronic pancreatic disease should be present: chronic indigestion, the passage of pale and bulky stools, glycosuria, perhaps jaundice from time to time, and colic if pancreatic calculus is present. *Peripancreatic* or *retroperitoneal cysts*, due to serous accumulations in the lesser sac of the peritoneum, or to growths originating in residues of the Wolffian body behind the peritoneum, may produce apparently identical cysts: the evidences of chronic pancreatic disease should be absent in these cases, but the diagnosis may be impossible until laparotomy has been performed. Cammidge's urinary reaction (p. 128) is said to be of assistance in diagnosing these cases.

Swellings in connection with the *duodenum* are felt in the right side of the epigastric and umbilical areas, and are usually due to primary malignant disease—a rarity. In many cases they escape palpation because they are so deeply placed, and they usually have to be diagnosed from such conditions as cancer of the stomach, pylorus, pancreas, bile-duets, and portal fissure generally, not by their physical signs but by the general symptoms and progress of the disease. A growth in the first part of the duodenum produces symptoms like those of cancer of the pylorus—wasting, anaemia, progressive dilatation of the stomach with visible peristalsis, attacks of copious vomiting, and occasional hæmatemesis perhaps; the motions contain bile, but the vomit does not; jaundice is absent unless there are secondary growths in the portal fissure. Malignant disease of the second part of the duodenum, in or involving the biliary papilla, soon produces obstructive jaundice and distention of the gall-bladder, and often leads to suppurative cholangitis, whereas cancer in the head of the pancreas or bile-duets produces steady jaundice and is not followed by suppuration in the bile-passages. Cancer in the third part of the duodenum or below the bile papilla produces duodenal stenosis, with dilatation of the duodenum and stomach and frequent vomiting; but in this case the vomit is habitually bilious and contains the pancreatic ferments. If there is no stenosis, the bilious vomiting will be less, and the case may be indistinguishable from one of cancer of the stomach. In most of these cases the exact diagnosis is more often made post mortem than ante mortem.

Swellings in connection with the *kidneys* and *suprarenal capsules* occur in the epigastrium only after they have reached a considerable size. They rise up out of the loin and flanks, and their diagnosis is considered below.

Enlargement of the *spleen* may bring its blunt anterior end or its notched upper edge into the epigastric area. The splenic swelling always lies in contact with the anterior wall of the abdomen, with the stomach above and internal to it (see SPLEEN, ENLARGEMENT OF THE, p. 774).

In every region of the abdomen *lymphatic glands* abound, and any of these may become palpable in cases of Hodgkin's disease, tuberculous peritonitis, or malignant disease. The enlarged glands are felt as nodulated chains or masses, usually hard and rounded, but softer and even cystic if their contents caseate or break down into pus; they may also calcify, when they become hard and stony. The enlarged glands that will be felt in the epigastric area are those connected with the stomach, liver, and mesentery; the diagnosis must be made on general and anatomical lines (see LYMPHATIC GLAND ENLARGEMENT, p. 471).

3. LEFT HYPOCHONDIAC REGION.

An abnormally lobulated *liver* may make a superficial tumour in this area continuous with the main mass of the liver in the epigastric region. In the same way, a tumour in the left lobe of the liver may project superficially into the left hypochondrium.

Part of the *stomach* lies in this region normally; the diagnosis of gastric swellings has been considered above. A gastric tumour may often be differentiated from a tumour of the adjoining spleen by the fact that while the spleen is anchored at its hilum, and so

is capable of but little movement, the stomach is highly mobile, changing its position with the position of the patient, and also in accordance with its fullness and distention : X-ray examination after a bismuth or barium meal may also help much.

The diagnosis of a tumour of the splenic flexure of the *colon*—scybulous, tuberculous, or malignant—is arrived at in the same way as in the case of a tumour of the hepatic flexure or transverse colon (see 1 and 2).

The diagnosis of the various causes of enlargement of the *spleen* is discussed under **SPLEEN, ENLARGEMENT OF THE** (p. 774). The tumour is usually to be recognized by the fact that it comes down from under the left costal margin in direct contact with the anterior abdominal wall, descends on inspiration, has a smooth surface, and a notched upper and inner margin. In exceptional cases, however, the enlarged spleen seems to adopt a more compact and cubical form in place of its usual elongated prismatic shape, and also to lie back in the loin and left lumbar region instead of occupying the anterior and upper part of the abdominal cavity ; it then simulates a tumour of the left kidney or suprarenal body, and unless the blood and leucocyte count give a definite lead the diagnosis may be settled only by a laparotomy. Conversely, a spleen-shaped hypernephroma or suprarenal tumour, or a calculous and cystic kidney, may easily be mistaken in an anæmic patient for an enlarged spleen, unless the possibility of the error be kept in mind.

Tumours of the *pancreas* may project into the left hypochondrium, as may also *retroperitoneal cysts* (see 2).

Tumours of the left *kidney* and *suprarenal body* rarely appear in the left hypochondrium unless they are very large (see 6 below). Unless very large they have the stomach or the stomach and colon in front of them, and so are variably resonant on percussion according to the amount of gas in those viscera—and are also less distinctly palpable than tumours arising from the spleen, stomach, colon, or omentum that may be felt in the same situation.

4. RIGHT LUMBAR REGION.

When the *liver* is abnormally lobulated, either congenitally or as the result of tight lacing, a thin flange of liver tissue, known as *Riedel's lobe*, may be met with as a superficial tumour, continuous with the liver above it, in this region. Sometimes it is freely movable, and then may be mistaken for a movable kidney or for a dilated gall-bladder.

The *ascending colon* can usually be palpated and rolled under the fingers as a tube-like structure at the confines of this and the umbilical region ; when empty and contracted it may feel almost rod-like. Its contents are usually fluid, but it may contain semi-solid or solid faecal masses that can be moulded by pressure, in constipated patients. In patients with obstruction lower down it may be greatly distended, and show sacculatation and visible peristalsis. It may become much thickened with inflammatory tissue, or even come to lie in an abscess of its own production, in pericolicitis, perityphlitis, typhlitis, appendicitis, and hyperplastic tuberculosis of the colon, forming a thickened and tender mass immediately under the abdominal wall ; the patient will be more or less acutely ill, with local pain and tenderness, constipation, often vomiting. In the more chronic of these cases, the diagnosis of malignant disease of the colon will often be suggested.

General thickening of the ascending colon, with tenderness and characteristic mucous or blood-streaked stools, is common in muco-membranous colitis, in dysentery, and in ulcerative colitis. The first of these is met with in nervous constipated women ; dysentery, amœbic or bacterial, is caught abroad, and is commoner in men than women ; while ulcerative colitis, whether it be dysenteric or not, is a severe and progressive painful diarrhoea, often associated with vomiting and irregular fever, that commonly leads to emaciation and death from exhaustion or intestinal hemorrhage in a year or two.

The ascending colon can be felt as a sausage-shaped tumour in acute, subacute, and chronic ilioæcal and ileocolic *intussusception* : at first in the right flank, then extending across the abdomen above the umbilicus, and finally down the left flank and into the pelvis. The chief symptoms are spasmodic abdominal pain, vomiting, the passage of blood and mucus by the rectum, and tenesmus ; the palpability and consistency of the elongated tumour vary according to the degree of muscular spasm in it. The diagnosis is generally established by laparotomy.

The *small intestine* is but rarely the cause of abdominal swelling in this region, excepting when it becomes the seat of enteric intussusception.

Tumours in connection with the *right kidney* and *suprarenal body* usually make their first appearance deep down in this region, having the ascending colon and small intestine in front of them. They can be lifted forwards *en masse* from behind by a hand placed at the back of the loin. For their diagnosis see KIDNEY, ENLARGEMENT OF (p. 437). The lower pole of the right kidney can be felt in normal persons on deep abdominal palpation; but when the kidney is abnormally mobile the whole of it may be felt, and in rare cases of *floating* as distinct from movable, it may be found in any of the adjoining abdominal areas. The shape and consistence of the movable kidney are characteristic, and the patient complains of a peculiar sickening sensation when it is grasped bimanually; in the lesser degrees of mobility it disappears readily into its normal position under cover of the diaphragm, and ceases to be palpable until the patient drives it down again by a deep inspiration. As regards its diagnosis, the movable right kidney will hardly be mistaken for anything else in this region; on the other hand, Riedel's lobe of the liver, the enlarged gall-bladder, faecal accumulations or a cancer of the ascending colon, and omental masses, have all been mistaken for it, although they are all superficial to the kidney, and lie in contact with the anterior abdominal wall. Other wandering tumours, e.g., of the ovary, Fallopian tube, mesentery, hydatid disease, may give rise to the same error if reniform.

5. THE UMBILICAL REGION.

Examination with the X rays after a bismuth meal has shown that the normal *stomach* is a far more mobile organ than was formerly supposed, and that in health its lower margin often descends below the level of the umbilicus; but if much of it habitually occupies the umbilical region in the horizontal posture, it is probably dilated to a pathological degree, either from atony (*Fig. 626*) or from pyloric obstruction.

Tumours in connection with the *transverse colon* have been considered under 1 and 4 above.

Tumours in connection with the *omentum* are common in this region: those arising from the *small intestine* are rare. Both are superficial, and their diagnosis has been given above (see 2).

Abdominal swellings in connection with the *urachus*, which runs from the umbilicus to the bladder, are considered below (see 8).

Swellings arising from the *duodenum*, *kidneys*, *suprarenals*, *pancreas*, and *mesentery* may all present themselves in the deeper parts of the umbilical region, usually as more or less fixed masses arising from or connected with some definite part of the posterior wall of the abdomen. Their diagnosis will depend mainly upon the success with which the origin and connections of the tumour can be made out: if the patient is fat, or if relaxation of the abdomen cannot be obtained, palpation under a general anæsthetic may be desirable. Consideration must also be given to any general symptoms such as may point to renal calculus, hydronephrosis, or pancreatitis, for example.

The *aorta* bifurcates half an inch below and just to the left of the umbilicus. In thin, nervous and excited patients, particularly young women, great pulsation of the aorta can often be felt in the umbilical and lower epigastric areas, and may lead to the wrong diagnosis of abdominal aneurysm. Careful examination will almost always show that this pulsation is no more than a throbbing, an up-and-down movement as the patient lies, without lateral expansile pulsation. Aneurysm of the abdominal aorta is very rare; it is seen in patients who have had syphilis; rare in men, it is almost unknown in women. The aneurysmal sac is distinctly larger than the normal aorta, and presents diagnostic expansile lateral pulsation met with in no other condition. These abdominal aneurysms often leak into the retroperitoneal tissues: large irregular clots of blood, weighing several pounds and of the most varied extent and distribution, may form gradually in the flanks,

Fig. 626.—Idiopathic dilatation of the stomach. The organ post mortem almost filled the abdominal cavity. (From Prof. Rutherford Morrison's *Introduction to Surgery*.)

pelvis, and back of the abdomen generally, causing the patient great pain by their situation and rendering him anæmic and breathless. The abdominal aneurysm also causes pain and stiffness in the back by eroding the bodies of the vertebrae upon which it presses.

6. LEFT LUMBAR REGION.

The enlarged *spleen* (see 3) may intrude into this area: it forms a firm mass, dull on percussion, and is in contact with the abdominal wall, driving the splenic flexure of the colon inwards or downwards before it. The spleen, when enlarged, comes down into the abdomen in front of all the other structures in the left side, and its abdominal dullness is continuous with its thoracic dullness, which extends back and up into the axilla along the line of the ninth or tenth ribs. Tumours of the stomach, omentum, suprarenal, kidney, or descending colon, may all be in contact with the anterior abdominal wall, and though usually nodular and irregular, may present a smooth and spleen-like surface on palpation. They may be distinguished from the enlarged spleen by the fact that they produce no such typical area of thoracic dullness in continuity with the dullness of the abdominal tumour; while the renal and suprarenal tumours may in addition be shown to occupy the back of the loin, so that they can be tilted forwards by the fingers placed behind just outside the edge of the erector spinæ muscles, and so pushed against the other hand which is placed on the anterior surface of the loin. A suprarenal tumour may be associated with sexual precocity (see *Figs.* 394, 395, p. 508).

The diagnosis of tumours of the *small intestine*, *kidney*, and *suprarenal gland* in this region has been given already.

7. RIGHT INGUINAL REGION AND RIGHT ILIAC FOSSA.

Abdominal swellings in the right inguinal region are rarely confined to it, and usually extend into the outer part of the hypogastric region, occupying what may be described somewhat indefinitely as the right iliac fossa.

New growths, inflammatory thickenings, and abscesses in connection with the *cæcum* and *appendix* may all extend into this region of the abdomen, giving rise to more or less acute and severe abdominal symptoms—pain, fever, vomiting, constipation, with a tumour in the right iliac fossa. The physical signs are very variable, depending on the extent and acuteness of the process, the degree to which the abdominal wall can be relaxed, the exact position of the tumour—an abscess to the inner side of and behind the cæcum and appendix may lie too deeply to be felt per abdomen. The rare condition of sarcoma or lymphosarcoma of the cæcum may be associated with fever; the tumour is soft, and the diagnosis of some chronic inflammatory condition will probably be made. A caecal carcinoma is usually a harder mass and of slower growth; it tends to constrict the bowel, with the result that fecal accumulation occurs behind it, and so the new growth may be overlooked when the hard mass of impacted feces is discovered. The diagnosis of appendicular abscess has been made in patients with movable right kidney during a Dietl's crisis; fever is usually absent in the latter; careful examination will generally show that the tumour in the right iliac fossa is an enlarged and movable kidney, and a history pointing to intermittent hydronephrosis, with polyuria after the acute attacks, should be obtainable. Pyclography (p. 445) will clinch the diagnosis. Inflammation of the right ovary or tube, or ovarian neuralgia occurring with the catamenia, may all give rise to symptoms in nervous patients that closely simulate those of appendicitis; and if scybala are present in the cæcum, vaguely felt as a tumour through the rigid abdominal wall, the mistaken diagnosis of appendicitis may easily be made; but as a rule pelvic symptoms and signs will be found, and pain be felt in the pelvic region and the lower part of the back; the diagnosis will be cleared up by a vaginal or rectal examination—which, indeed, should never be omitted when there is any doubt as to the exact causation of an inflammatory swelling in the iliac fossa—and by the previous history of the case.

Inflammatory swellings and abscesses in the right iliac fossa may arise in connection with *psoas abscess*, *abscess* originating in the *sacro-iliac joint*, *hip-joint*, or *ilium*, and from the swelling or breaking down of *lymphatic glands* (the external iliac) infected from some perhaps trivial wound in the leg or perineum. The symptoms of bony disease about the hip or the pelvic girdle will be present; the leg will be held more or less stiffly in some

abnormal attitude of flexion and inversion to relieve the pain, and movement of the leg will be painful. Unless local peritonitis is present there will be none of the special symptoms that point to appendicular or caecal disease.

8. HYPOGASTRIC REGION.

In rare instances, tumours arising in the *small intestine*, and more often the sausage-like swelling of an enteric intussusception, may be felt in the hypogastric area (see 4). Tumours extending into it from the iliac fossae are described under heading 7 above and 9 below.

In infants, the *bladder* reaches half way to the umbilicus when moderately full and does not fall below the pubic symphysis when empty. In the adult, the distended bladder is a common hypogastric swelling, particularly in females with *retroverted gravid uterus*, in males of about sixty with *enlargement of the prostate*, or in patients of either sex with morbid changes in the spinal cord *spastic paraplegia* or *tubes dorsalis*, for example: it may reach up as an ovoid elastic mass arising from the front of the pelvis almost to the umbilicus under conditions that are in no way pathological, as well as when the retention is due to some pathological cause. Such a distended bladder (*Fig. 627*) has been tapped as ascites, operated upon as ovarian or urachal cyst, and diagnosed as the pregnant uterus: mistakes that are not likely to occur if these possibilities be remembered, and are put out of court by micturition or the use of a catheter before the diagnosis is made.

The *urachus* is a fibrous cord running in front of the peritoneum from the top of the bladder to the umbilicus, in the middle line: it sometimes becomes the seat of cyst-formation, more often in women than in men. The urachal cyst is a rounded tumour lying between the umbilicus and pubes, soft or firm according to the tension of its contents: it may produce hypogastric pain. It must be distinguished from encysted tuberculous peritonitis, from ovarian cystadenoma, and from the distended bladder.

Abdominal swellings arising from the *uterus*, *ovaries*, *tubes*, and *uterine ligaments* may all rise up out of the pelvis and present themselves as swellings in this region, and, as they grow larger, may spread into the whole or any part of the abdomen. While they are comparatively small and manifestly connected with some intrapelvic organ their origin is not difficult to determine; their diagnosis is considered under SWELLING, PELVIC (p. 840). But when they have grown up into the abdomen, or have acquired a long pedicle, or have become fixed by adhesions to some distant part of the abdominal wall or to some other viscus, perhaps causing it to become inflamed and impairing its functional activity, these pelvic tumours may give rise to signs and symptoms suggesting any disease rather than one that is pelvic, and the true diagnosis may be very difficult to make. The possibility of pregnancy in the female should always be remembered.

9. LEFT INGUINAL REGION AND LEFT ILIAC FOSSA (see 7 above).

The *sigmoid flexure of the colon* can be felt normally as a tube-like cord passing from the left lumbar region down into the pelvis, and rolled under the fingers. It very frequently contains hard ovoid scybalous masses. In rare instances it may be uniformly thickened and tender in consequence of chronic inflammation, tuberculous or otherwise. It is occasionally the seat of cancerous new growth, when the patient will complain of chronic intestinal obstruction, with cachexia, tenesmus, and the passage of blood-stained stools, phenomena that may also be met with in hyperplastic or stenotic tuberculosis of the sigmoid.

Fig. 627.—Idiopathic dilatation of the bladder. The physical signs were those of a cystic tumour occupying the lower part of the abdomen. (From Professor Rutherford Morrison's 'Introduction to Surgery'.)

The left iliac fossa may be the seat of abscess or inflammations similar to those described under 7 above. In addition, suppuration around an exaggerated colonic diverticulum, with symptoms not unlike those of appendicitis on the wrong side, has been known to occur; such a condition is termed *acute diverticulitis* of the colon. *A. J. Jea-Blake.*

SWELLING, AXILLARY. Swelling in the axilla is due in the great majority of cases to enlargement, from one cause or other, of the lymphatic glands; a subsequent abscess, either acute or chronic, is frequent. Any other form of tumour is distinctly rare. In examining a case, therefore, these two causes should be uppermost in the mind, and indeed, on inspection only, the diagnosis may be obvious, e.g.:

Acute Abscess may be recognized at once by the well-marked signs of local inflammation and the general febrile disturbance. There is one form of acute abscess that may not be obvious, namely, one situated in the upper part of the axilla and covered by the pectoral muscles. On account of its distance from the surface the local signs of inflammation may not be great, though the general signs are marked. There will be great disinclination to move the arm on account of pain, and there is usually some cause, such as a whitlow on the finger, to account for the trouble. It must be remembered, however, that the abscess may be 'residual': that is to say, the original source of infection, such as the whitlow, may have healed completely two, three, or even more weeks before the axillary abscess declares itself. Occasionally an empyema points in the axilla: there are generally, but not always, abnormal lung signs to suggest the diagnosis.

Chronic or Tuberculous Abscess forms a single fluctuating swelling which, if large, may extend upwards under the pectoralis major. Owing to the fact that few, if any, of the local signs of inflammation may be present, difficulty arises in distinguishing this form of abscess from a soft lipoma. The duration and the rapidity of growth of the swelling are a good guide, for though the duration of a chronic abscess may run into months, it does not exist for years, as does a lipoma.

Enlargement of the Lymphatic Glands. Next, supposing that examination proves that the swelling is not an abscess, attention should be directed to ascertain whether it is glandular, and it is therefore necessary to recall the anatomical position of the glands. The axillary lymphatic glands are ten to twelve in number, and are arranged in three sets. One chain surrounds the axillary vessels and receives the lymphatics from the arm; a small chain runs along the lower border of the pectoralis major as far as the mammary gland, receiving the lymphatics from the front of the chest and the breast: the third chain is placed along the lower margin of the posterior wall, to receive lymphatics from the integuments of the back. If the glands are affected in any way, all need not necessarily be enlarged, but it would be extremely unusual if only one were picked out, and commonly two or three, or one entire group, are affected. Therefore axillary swellings due to glandular enlargement are almost always multiple, and are situated in the part of the axilla where glands are normally present. This may not be quite accurate when much inflammation has occurred around the glands and they are matted together, as happens with tuberculous infection: but even then the mass may be felt to be made up of many glands. For the differential diagnosis of glandular swellings, see LYMPHATIC GLAND ENLARGEMENT (p. 471).

Primary Tumours of the Axilla are distinctly rare.

Lipoma is the most common. It may attain a large size and extend up under the pectoral muscles. It should be diagnosed by its long history, slow growth, definite outline, and free mobility. When very soft, the tumour may give the feeling of fluctuation, and so be mistaken for a chronic tuberculous abscess. The skin wrinkles when one attempts to raise it away from the tumour.

Cystic Hygroma of the axilla is very rare. It is usually congenital. It forms a soft, fluctuating, painless swelling, which sometimes grows rapidly. It may easily be mistaken for a lipoma, and the diagnosis is seldom certain until microscopical examination has been made after excision.

Primary Malignant Tumours may arise, but are of extreme rarity.

Aneurysm of the Axillary Artery does occur, but is uncommon. It is recognized easily because it is comparatively superficial and it gives an expansile pulsation synchronous

with the heart's beat ; the veins of the forearm may be distended on account of pressure on the axillary vein, and the radial pulse on the affected side is diminished in size and delayed. There may be a definite history of local injury, or in cases of apparently spontaneous aneurysm there may be signs or symptoms of fungating endocarditis (p. 45).

George E. Gask.

SWELLING ON A BONE. It is presumed that the swelling has been ascertained to be of the bone, immovable apart from it, and that it is not merely some tumour lying close to it.

The following method of examination should be adopted : (1) Inquiry into the clinical history, mode of onset, duration ; (2) Search for the signs of inflammation ; (3) Evidence as to whether the swelling is a localized projection or involves the whole circumference of the bone ; (4) Investigation for involvement of other bones or further signs of disease, e.g., tuberculosis, syphilis, rickets, etc. ; (5) A skiagram should always be taken if possible ; (6) If a discharge is present, a bacteriological examination should be made.

The various swellings may be classified under the following headings : -

(I) *Injury* ; (II) *Infective Diseases* ; (III) *General Diseases*, not limited to one bone ; (IV) *Tumours* ; (V) *Cysts*.

I. INJURY.

A blow or kick may give rise to a swelling due to *extravasation of blood* or serous fluid under the periosteum. This disappears rapidly, but may leave a small permanent thickening or node. Such a node is found not infrequently on the shins of football players. A fracture of bone is followed by the formation of *callus*, which forms a large swelling if the broken ends do not lie in accurate apposition, or if there has been too much movement between them. After four to six weeks the callus begins to be absorbed, and it may disappear entirely ; in most cases a small permanent swelling indicates the site of fracture. A green-stick fracture may not show any swelling at first, and may be overlooked on this account, being discovered only when the formation of callus draws attention to it.

II. INFECTIVE DISEASES.

These give rise to inflammatory changes in bone, the signs of which are more or less obvious according to the nature and virulence of the infection. These changes have usually been named according to the chief starting-point (periostitis, osteomyelitis, etc.), though they seldom remain confined to one particular part of the bone. Classification may be made according to the nature of the infecting organism, viz., pyogenic (staphylococci and streptococci), tubercle, syphilis, etc.

Infection with Pyogenic Organisms.

Acute infection may occur through wounds or injuries, or via the blood-stream. The resulting swelling is due to the formation of pus between the periosteum and the bone ; this may be a localized abscess, or the whole of the periosteum may be stripped off and the bone lie bare in a bag of pus. The disease usually occurs in young people, and the intimate attachment of the periosteum at the epiphyseal lines limits the spread of suppuration ; in long-standing cases the pus may burrow farther and even burst into the joint. Suppuration is rarely limited to the surface of the bone, but spreads into the marrow, causing osteomyelitis ; lymphatic absorption and septic embolism are liable to give rise to a general blood-infection and pyæmia.

The signs of inflammation are abundant : the swelling is acutely painful and tender, the skin over it red and oedematous, and the constitutional signs of fever are marked. If the blood is examined, a high leucocytosis will be found. Rigors are usual.

It is important not to mistake *erythema nodosum* for this affection ; in erythema nodosum the red swellings are generally multiple, bilateral, and confined to the shins ; it is rare for acute osteomyelitis to be bilateral and symmetrical, and confined to the parts between the knees and the ankles.

Chronic Infection. Such a condition as detailed above may become chronic and cause a swelling which may last for months. If the pus formed under the periosteum escapes, either by bursting or through an incision, sinuses form, and the periosteum, in the process

of repair, becomes thickened. If during the height of the inflammation a portion of the bone has died (necrosis) this dead bone is virtually a foreign body which keeps up inflammation and suppuration: great thickening of all the constituent parts of the bone

results (*Fig. 628*). Usually the diagnosis can be arrived at without difficulty. Occasionally, if the inflammatory changes have not been great, and the amount of necrosis is small and deeply-seated (central necrosis), a condition resembling a slow-growing sarcoma may result. A skiagram may serve to show that the chronic inflammatory periosteal thickening is added on to or 'applied' to the original compact layer of bone, whereas in the case of sarcoma, though there may be thickening and formation of bony or calcareous spicules in the growth, the compact layer is eaten away (*Figs. 635-642*, pp. 824-823). However, this may be somewhat slender evidence on which to base the diagnosis between so important a condition as sarcoma and inflammation, and if doubt arises an incision should be made into the tumour,

Fig. 628. Skiagram from a case of chronic periostitis of humerus and radius due to chronic pyogenic infection. (*Fig. Dr. Alfred C. Jordan.*)

so that a portion may be removed for microscopic investigation.

The precise nature of either acute or chronic pyogenic infection of a bone is determined by skilled bacteriological investigations upon appropriate material obtained from the part: staphylococci or streptococci are the commonest organisms producing the condition, but clinical evidence alone may not suffice to exclude rarer causal organisms such as pneumococci, pneumobacilli, gonococci, typhoid bacilli, paratyphoid bacilli, dysentery bacilli, influenza bacilli, *Bacillus pyocyaneus*, *Bacillus mallei*: or there may be one or other of these secondarily infecting chronic lesions due to tuberculosis, actinomycosis, leprosy, leprothrix, or hydatid disease.

Tuberculous Disease generally starts in the cancellous tissue of the small bones of the carpus, tarsus, or phalanges, or at the ends of long bones. The inflammatory changes, which are slight, give rise to caries of the affected bone: the external signs of inflammation are little marked, and it is comparatively rare for any swelling of the bone to result, though the soft parts around the bone may be swollen considerably.

Tuberculous dactylitis furnishes an instance in which the disease forms a periosteal swelling. It is found most often in quite young children, and the bones commonly affected are the metacarpal bones and phalanges of the hand (*Figs. 629, 630*). The affected digit exhibits a fusiform enlargement, slightly tender, tending to diminish after weeks of rest.

Tuberculous periostitis may develop in any long bone, on the ribs or the humerus most commonly, and it then has to be differentiated from syphilis by finding the Wassermann reaction negative, or by obtaining no improvement after antisyphilitic treatment with mercury, iodides, and salvarsan.

Chronic tuberculous abscess of bone occurs most frequently in the young adult, and nearly always in the articular extremity of a long bone, by preference in the upper end of the tibia. Enlargement of the bone is found only when the abscess approaches the

Fig. 629. Skiagram from a case of tuberculous dactylitis affecting the first phalanx of the middle finger in a child. (*Fig. Dr. C. Thorstein Holmboe.*)

surface and involves the periosteum. The skin then becomes a little red and oedematous, and there is generally a small spot that is exquisitely tender on firm pressure. When secondary infection with pyogenic organisms occurs a not infrequent event all the swellings described under 'acute infection' may result. A skiagram will generally reveal the true condition: if not, a diagnostic injection of Koch's old tuberculin may be made, or von Pirquet's skin reaction tested.

Syphilis in the acquired form may lead to periosteal thickenings in the secondary stage and to gummata in the tertiary. The former give rise to excessively tender swellings ('nodes') on the surface of the tibiae, clavicles, sternum, ribs, or skull. They are generally multiple, two or three often being found on the same bone. The patient complains of pain, particularly in bed, when the extra warmth causes further dilatation of already inflamed vessels. Relief is given almost at once by potassium iodide. Sometimes one of these swellings is followed by the formation of compact periosteal bone, giving rise to a node which fades gradually into the surrounding parts, like a hill rising gently from a plain.

Gummata may form localized swellings, or may invade the whole substance of the bone, causing osteomyelitis and general thickening (Fig. 631). The condition has to be distinguished from tuberculosis, chronic pyogenic infection, and sarcoma: such recognition is arrived at by means of the Wassermann test, and the fact that antisyphilitic remedies cause a marked and rapid improvement. Diagnosis by incision has rarely to be resorted to.

In *congenital syphilis* two forms of bony swelling are common: (a) Periosteal thickenings of the bones of the vault of the skull, called Parrot's nodes—the hot-cross bun or natiform skull. (b) In new-born infants, epiphysitis and separation of the epiphyses: so painful is a limb thus affected that it is kept motionless, and may be thought to be paralysed.

Typhoid Fever. In the course of this disease a periosteal node or abscess may form. From the fluid a pure culture of typhoid bacilli may be obtained perhaps for a long time after the fever. The nodes by no means always break down into pus.

III. GENERAL DISEASES NOT LIMITED TO ONE BONE.

Rickets. The ordinary form is well known, and can hardly be confused with any other disease.

Scurvy rickets is quite distinct from rickets. It arises generally in infants under twelve months old who have been fed too exclusively on artificial foods or preserved milk. The disease therefore is more common among the children of the rich than the poor. The child is often brought to the doctor on account of the sudden appearance of an exceedingly painful swelling of a long bone, such as the femur. The swelling may fluctuate, and yield on aspiration blood-stained fluid. Spontaneous fracture is liable to occur. The diagnosis is indicated by the fact that the child is anemic, and has spongy gums and hæmorrhages from the mucous membranes. The condition is most likely to be confused with acute suppurative periostitis or traumatic fracture.

Fig. 631. Skiagram showing typical syphilitic disease of the radius. The ulna is normal. (Fig. Dr. C. Thørlund, Holland.)

Fig. 630. Skiagram from a case of tuberculous disease of the metacarpal bone of the thumb in a child. (Fig. Dr. C. Thørlund, Holland.)

Osteitis deformans (Fig. 632, and Figs. 159–161, p. 193) is a senile disease, very chronic, and characterized by thickening, lengthening, and bending of the bones. The whole osseous system may be affected, but attention is first drawn to the disease by thickening of the tibiae and forward bending of the knees,

or sometimes by enlargement of the head. In the rare event of one bone only being affected it may be confused with syphilitic osteitis, and only be recognized on the failure of antisiphilitic remedies and by the subsequent involvement of other bones. The patient suffers from neuralgic pains, and in the later stages from dyspnoea. In such cases death sometimes occurs from the development of multiple sarcomata of the bones.

Acromegaly (Fig. 250, p. 293) is described on p. 293.

Leontiasis Ossæa. In this disease there is general overgrowth of the cranial and facial bones, and one of the chief symptoms may be the fact that the patient has to get progressively increasing sizes of hats. (See p. 254, and Fig. 215, p. 255.)

Swellings of bones associated with diseases of joints may be found in *gout*, *osteo-arthritis*, and *pulmonary hypertrophic osteo-arthropathy*. (See JOINTS, AFFECTIONS OF, p. 423.)

Fig. 632.—Osteitis deformans producing swelling and deformity of the left radius.

IV. TUMOURS.

These are (1) *Innocent*; and (2) *Malignant*. Innocent tumours as a whole are characterized by their long history, slow growth, localized projection, and the absence of all signs of inflammation.

1. Varieties of Innocent Tumours.

Osteoma or *exostosis* is the commonest form (Fig. 633). The usual site is in the neighbourhood of the epiphyseal line of a long bone, particularly the lower end of the femur: the tumour is capped

with cartilage, and often surmounted by an adventitious bursa containing fluid.

The ungual phalanx of the great toe is another common site for a similar tumour which pushes up the nail and may be very painful if ordinary boots are worn. Multiple exostoses are not uncommon, and they may be hereditary. Diagnosis can be made at once by means of a skiagram, and with this aid it can be seen that the swelling is composed of cancellous tissue continuous with that of the bone. A spurious osteoma may arise by

location of a tendon or by an extension of the ridge which the tendon is inserted, the condition being generally consequent on some injury or repeated strain, as in the case of horse-riders, who are apt to develop one on the inner aspect of the knee: another example is the spur that is apt to form on the under surface of the os calcis at the posterior end of the long plantar ligament, giving rise to much discomfort and even acute pain below the heel in walking. A skiagram may be required in establishing the diagnosis with certainty (Fig. 429, p. 541).

Ivory exostoses may be found on the flat bones of the skull, or in the auditory meatus growing from the petrous bone, or causing unilateral exophthalmos if springing from the orbital plate of the frontal bone or the walls of the frontal sinus.

Chondromata may grow from any bone except the flat bones of the skull. They are most commonly multiple, affecting the phalanges and metacarpal bones of the hand (Fig. 634). The result is increasing deformity, with pain and ultimately ulceration of the skin.

Fig. 633.—Skiagram of a common variety of cancellous exostosis of the femur.

Fibromata grow from the fibrous tissue of the periosteum, but are rare except in the form of an epulis of the jaw. (See SWELLING OF THE JAW, LOWER, p. 834.)

Lipomata of bone are extremely rare. They grow from the outer layer of the periosteum.

2. Malignant Tumours may occur either primarily (sarcoma), or secondarily by metastasis or by invasion (sarcoma and carcinoma).

Periosteal sarcomata are of so many types, and of such varying degrees of malignancy, that it is difficult to lay down any rule as to their characteristics. The softer their consistence and the nearer they approach to the embryonic type of tissue, the more malignant they are; while the more they resemble the fully-formed tissues and contain cartilage, bone, or fibrous tissue, the slower growing and less malignant they are. A typical case may be represented as a rapidly growing tumour, generally about the end of a long bone (Figs. 635, 636). It is not usually painful, and the signs of local inflammation and general fever are little marked, or absent. The patient is commonly a young adult, who often gives a history of injury to the part, and may lose weight and strength before actual cachexia sets in. The veins over the swelling become prominent, the lymphatic glands enlarged, and metastases by the blood-stream occur early, especially in the lungs. It has to be distinguished from chronic and syphilitic periostitis. If a skiagram is insufficient a piece of the tumour

Fig. 634. Skiagram of multiple enchondromata of the hand. Note the tendency to their confinement to the ulnar portion of the hand; in other cases they may similarly be confined to the radial two thirds, as if they were subject to a nervous distribution. There is a small enchondroma in the lower end of the ulna, a large one in the 5th metacarpal, a small one in the 4th metacarpal, and they are multiple in the 1st, 2nd, and 3rd phalanges of the little finger, and in the 1st and 2nd phalanges of the ring finger.

Gout may sometimes produce not entirely dissimilar appearances (see Fig. 342, p. 130). (By Dr. C. Thurstan Holland.)

Fig. 635. Skiagram of a periosteal sarcoma of the outer aspect of the upper end of a femur. The striations in the tumour, running at right angles to the shaft of the bone, are characteristic. The diagnosis was confirmed by operation and microscopical examination. (By Dr. C. Thurstan Holland.)

Fig. 636. Skiagram of a periosteal sarcoma of the shaft of the humerus, involving the latter all round for over half its length. The striations in the tumour, at right angles to the shaft of the bone, are characteristic. The diagnosis was confirmed by histological examination. (By Dr. C. Thurstan Holland.)

may have to be excised, decalcified, and a microscopic section prepared from it. This form of sarcoma is the worst possible, and seeing that amputation does not cure, and

often does not prolong life, this extreme resource may be delayed where either gumma or chronic periostitis is still a possible diagnosis.

Endosteal or myeloid sarcomata, myelomata, are of much slower growth; so slow are they that some pathologists are inclined to denote them as benign tumours. They

Fig. 637.—Skiagram of a chondrosarcoma of the lower end of a femur. The tumour is not of central origin as a myeloid sarcoma is (see *Fig. 640*), and the opacities in the tumour are not radially striated as are those of a typical periosteal sarcoma (*Figs. 635 and 636*). The diagnosis was confirmed by histological examination. (*By Dr. C. Thurstan Holland.*)

Fig. 638.—Skiagram of a myeloid sarcoma of the upper end of the humerus; showing great expansion on the latter, and disappearance of the ordinary shadow of the head and upper part of the shaft. The diagnosis was confirmed by histological examination. (*By Dr. J. H. Mather.*)

Fig. 639.—Skiagram of a myeloid sarcoma of the upper end of the tibia. The tumour arises centrally, and as yet it has not expanded the bone much. Skiagraphically alone it could not be distinguished from an enchondroma. The diagnosis was confirmed by histological examination. (*By Dr. C. Thurstan Holland.*)

Fig. 640.—Skiagram of a myeloid sarcoma of the upper end of the tibia. The tumour arose centrally, but it has expanded the bone materially. The diagnosis was confirmed by histological examination. (*By Dr. J. H. Mather.*)

are prone to affect the ends of the long bones (*Figs. 638-641*), particularly the lower end of the femur, the upper end of the tibia, the upper end of the humerus, the lower end of the radius, the sternal end of the clavicle, and the upper jaw (malignant

epulis). Attention is first called to the part by pain; then a more or less uniform swelling appears. This is at first bony hard, and only as the shell of bone yields does softening occur, or crackling on pressure. The lymphatic glands are not enlarged, and metastases do not occur. In the early stages diagnosis has to be made from rheumatism and chronic abscess, and later from chronic osteomyelitis and periosteal sarcoma: it is easily made by the aid of X rays as a rule, but it is most important not to mistake the callus that is produced after fracture for a sarcoma: this mistake is not always

Fig. 641.—Sklerogram of a medullary sarcoma of the lower end of the femur, showing the appearance after the tumour, arising centrally, has expanded the bone until ultimately the neoplastic growth has extended beyond the confines of the original bone. The diagnosis was confirmed by histological examination. (Dr. J. C. Thurston, Holland.)

Fig. 642.—Sklerogram of a sarcoma of radius and ulna; the growth surrounds the bones and is eating into them; it was not primarily a bone growth. (Male, age 28.) (Dr. J. C. Thurston, Holland.)

obviated even by the use of the X rays, unless the latter reveal the line of fracture as well as the callus around it. Sarcoma may also invade the bones from outside, having started in the subcutaneous or deeper soft tissues outside the bone (*Fig. 642*).

Carcinoma is always secondary (*Fig. 156*, p. 190). Squamous-celled carcinoma may spread to the tibia from an epitheliomatous ulcer of the leg, or to the jaw from the lip or floor of the mouth. It is mostly spheroidal-celled carcinoma which infects bone by metastatic growths, particularly from the breast or from the thyroid gland. A swelling of the bone may be found, but this is rarely discovered until attention is called to it by a spontaneous fracture.

Hypernephroma sometimes leads to secondary deposits in bones.

V. CYSTS.

Blood cysts are found in degenerating sarcomata.

Hydatid cysts are uncommon in this country. They affect the diaphyses of the long bones, converting the shaft into a thin-walled tube which undergoes spontaneous fracture. They would hardly be suspected unless there was known to be hydatid disease elsewhere, especially in the liver.

Cysts of the jaw, or *dentigerous cysts*, are considered in the article on SWELLING OF THE JAW, LOWER (p. 834).

George E. Gask.

SWELLING OF THE FACE.—In this article are included only swellings of the skin and subcutaneous tissues. Malignant and other diseases of the facial bones, etc., are considered under SWELLING OF THE JAW (p. 834), and SWELLING ON A BONE (p. 817). SWELLING OF THE SALIVARY GLANDS is discussed on p. 848. Contusions and injuries to the face are so obvious that they need no mention. The remaining swellings will be classified as (1) *Non-inflammatory*; and (2) *Inflammatory*.

1. Non-inflammatory Swellings.—

Renal and Cardiac (Edema).—If the whole face is puffy and the eyelids are oedematous, the urinary and cardiac systems are to be examined for disease. For swelling due to *obstruction of the superior vena cava* by mediastinal fibrosis, aneurysm, or new growth, see OEDEMA (p. 511), and VEINS, VARICOSE THORACIC (p. 910).

Angioneurotic (Edema) is a disease characterized by the occurrence, sometimes periodical, of local oedematous swellings, more or less limited in extent and of transient duration. It is not confined to the face, but the eyelid is a common situation (*Fig. 407*, p. 513), and also the lips and cheek. It may be simulated closely by *urticaria* following the taking of fish or pork; or by a somewhat similar effect produced by some drugs, notably aspirin in certain patients.

Tumours are not common. They may be fibroma, lipoma, epithelioma, or sebaceous cyst.

Inflammatory Swellings. Often the cause is obvious: for instance, a *boil*, *carbuncle*, or *suppurating wound*; or the 'blubber-lips' that result from chronic *lymphangitis*.

Erysipelas is prone to occur on the face. It is marked by a vivid red oedematous swelling, associated with fever. The redness tends to spread, the edges being raised and well defined from the healthy skin. The oedema may be continuous, or it may disappear in one place and re-appear in another. In very severe cases the fever is high, rigors occur (*Fig. 556*, p. 699), the cuticle may be raised in blebs, and sloughing may ensue.

Alveolar Abscess and *Dental Caries* are fertile sources of facial swelling, also abscess in the nasal sinuses. (See SWELLING OF THE JAW, p. 834.)

Anthrax chiefly affects operatives in wool and horse-hair factories and workers of raw hides. The disease is characterized by the formation of a vesicle, which bursts, forms a scab, and then becomes surrounded by a ring of vesicles, and around this is an area of oedema. The diagnosis is made by the microscope. A film prepared from a drop of fluid from one of the vesicles contains long chains of large, square-ended, Gram-staining bacilli, which have a characteristic growth on culture media.

Vaccinia.—An accidental infection about the face may be mistaken for an anthrax pustule. If inquiry into the attendant circumstances is not sufficient to exclude the graver disorder, a bacteriological examination should be made.

Primary Syphilitic Sore, if found on the face (*Fig. 94*, p. 94), is generally situated on the upper lip, though it may also occur upon an eyelid (*Fig. 382*, p. 473), the nose, or elsewhere. It is not so indurated as when on the glans penis, but the surrounding oedema is more marked, and the neighbouring lymphatic glands become enlarged. The condition is often missed because it is not expected. An absolute diagnosis can be made by finding the spirochæta in the serum discharged from the ulcer, and by Wassermann's test, though the latter may not yet be positive if the facial chancre is of recent date.

Insect Bites or Stings from mosquitoes, gnats, bees, etc. often cause large, lumpy, irritating swellings. The only difficulty in diagnosis is when the original bite or sting has become indistinguishable owing to infection with pyogenic organisms.

The various skin diseases which may be associated with swelling of the face are considered under PUSTULES (p. 681); VESICLES (p. 913); WHEELS (p. 934); etc.

George E. Gask.

SWELLING, FEMORAL. By the femoral region is meant Scarpa's triangle. It is easy to define on paper what a femoral swelling is, but in a fat patient it may be very difficult. The two great landmarks which, with care, can always be made out, however fat the patient, are the spine of the pubes and the anterior superior spine of the ilium; a line joining these two points and curving slightly downwards separates the inguinal from the femoral region, and indicates Poupart's ligament. Mistakes are often made, especially in fat people, because a horizontal crease in the thigh which lies below sometimes as much as two inches below is mistaken for the ligament. The first point in making

the diagnosis is to decide definitely that the swelling is femoral, and then to decide its nature.

It may be obvious at once what the swelling is : for instance, a well-marked acute abscess, with redness and œdema of the skin and an undoubted source of infection, such as a sore toe ; or, a rare occurrence, an aneurysm of the femoral artery, showing expansile pulsation. Supposing, however, the signs are not so clear, the various conditions may be classed broadly under two heads : (1) *Swellings that are reducible and give an impulse on coughing* ; (2) *Swellings that are irreducible and do not give an impulse on coughing*.

1. Reducible Swellings with an Impulse are : (a) Femoral hernia (reducible) ; (b) Saphena varix ; (c) Psoas abscess. All these give an impulse on coughing : are, or may be, reducible on pressure ; may disappear on lying down and reappear on standing. How then is one to distinguish between them ?

a. Femoral Hernia (reducible). The sex of the patient is no real guide, for though it is more common to find a femoral hernia in a woman than in a man, this is not sufficient to base the diagnosis on. Before puberty it is rare in either sex. A femoral hernia leaves the abdomen through the femoral canal and turns directly forward, forming a tumour in the upper and inner part of the femoral region ; then, following the line of least resistance, it turns upwards, extending often above Poupart's ligament, thus simulating an inguinal hernia. More rarely, the hernia extends downwards along the femoral vessels. Its course must be remembered in attempting to discover whether the swelling is reducible. If it is large and contains intestine it will be resonant, and a gurgling may be heard or felt on reduction, distinguishing it at once from all other femoral swellings. If it is reduced and the finger held over the femoral aperture, the hernia will be felt projected forcibly against the finger when the patient is asked to cough. If a swelling is complained of, and none is found even on standing and straining, it is suggestive of femoral hernia with only occasional descent, and the patient should be examined at another time after exercise.

b. Saphena Varix is a localized dilatation of the saphenous vein at the saphenous opening, immediately before it joins the femoral vein. It may easily be confounded with a femoral hernia, for it forms a swelling in the ordinary position of a femoral hernia, it disappears on lying down, reappears on standing, and gives an impulse on coughing. A little care, however, should suffice to distinguish the two. The impulse is quite different : in a saphena varix it is more in the nature of a thrill, such as may be felt in a varicocoele or in big varicose veins in the leg. If, while the patient is standing, a finger is pressed on the swelling, it collapses gradually, and as the finger is withdrawn the swelling follows, regaining its shape like an air-ball, whereas a hernia comes out with a pop. A saphena varix is almost always associated with varicose veins in the leg, though none may show between the knee and Scarpa's triangle.

c. Psoas Abscess. The need to differentiate between this and the two conditions mentioned above exists only when the abscess has extended from the iliac region, has passed under Poupart's ligament and the femoral vessels, and is pointing in the inner part of Scarpa's triangle. There is an impulse on coughing and the swelling is reducible : but another swelling is to be found above Poupart's ligament, and fluctuation is to be obtained between the two. Conclusive proof can be found by an examination of the back. This should be made with the patient standing and the whole length of the back and the hips exposed. An undoubted angular kyphotic curve may be seen at once, or, if that is not present, there may be rigidity and impaired movement denoting some disease on the anterior surfaces of the bodies of the vertebrae.

2. Irreducible Swellings without Impulse : (a) Femoral hernia (irreducible) ; (b) Lymphatic glands inflammatory or malignant ; (c) Primary tumours lipoma, fibroma, sarcoma ; (d) Ectopic testis.

a. Femoral Hernia (irreducible). The irreducibility may be accounted for in four ways : (i) Strangulation ; (ii) A piece of omentum adherent to and plugging the neck ; (iii) An empty sac, but a mass of extraperitoneal fat round it ; (iv) A hydrocele of the sac.

If strangulation has occurred there will be the signs of intestinal obstruction, viz., vomiting and absolute constipation. It must be remembered that the swelling may be but a small one, and when the patient is very fat it may be missed.

It is usual to find around the sac of a femoral hernia a quantity of extraperitoneal fat,

even in a thin person, and it is quite impossible to say without dissection whether the swelling is due to a plug of omentum inside the sac or to a collection of fat outside it.

A hydrocele may be formed as a result of a long-standing hernia into which there has been no descent of bowel or omentum, and in which the communication with the general peritoneal cavity has become constricted or closed. The sac may then become cystic and filled with fluid. Fluctuation may be obtained in the swelling, though it is often only on dissection that the exact nature of the condition is revealed. A hernial swelling is single, and though it may be movable in some directions it is always tied down by its neck to the aperture of the femoral canal.

b. Enlarged Glands may be : (i) Inflammatory ; (ii) Malignant (see p. 476).

Chronically inflamed glands may be hard to differentiate from a small irreducible femoral hernia. The whole limb is to be examined to see whether there is any possible source of infection, and the whole patient to see whether there is a general enlargement of the glands, as in lymphadenoma. The chief distinguishing feature between the two conditions is that femoral hernia forms only one swelling, whilst it is rare for only one gland in its group to be picked out by an infecting agent. Therefore, if there is more than one swelling the chances are that these are glands. Perchance both conditions are present, a femoral hernia and enlarged glands—a very difficult combination unless the femoral hernia happens to be reducible or gives an impulse on coughing. In such a case an attempt should be made to feel the neck of the sac running up to the femoral canal.

c. Primary New Growths are rare in this situation. They may be lipoma, fibroma, or sarcoma. The innocent tumours are noted for their free mobility in all directions. A primary sarcoma is diagnosed rather by exclusion and by its malignant characteristics.

d. Ectopic Testis. One of the places into which a testis may be drawn abnormally is Scarpa's triangle, which it reaches by passing over Poupart's ligament. The facts that the swelling has the shape of the testis, though generally smaller than normal, and that the corresponding half of the scrotum is empty, make the diagnosis easy.

Certain swellings are neither truly femoral nor truly inguinal, but betwixt and between, bulging Poupart's ligament forwards. They are generally deep, and on that account obscure. They may be due to :

1. Distention of the hip-joint, as in tuberculous disease of the hip.
2. Distention of the bursa between the tendon of the ilio-psoas muscle and the capsule of the hip-joint. If large, the swelling may be quadrilateral in shape, and owing to its sensitiveness to pressure the leg is kept in the position of greatest ease, i.e., slightly flexed, abducted, and externally rotated. This condition is often difficult to distinguish from psoas abscess or from distention of the hip-joint, with which, indeed, it often communicates. Diagnosis may be aided by puncturing the swelling with an aspirating needle.
3. Osteophytic outgrowths from the acetabulum in osteo-arthritis of the hip-joint.
4. A parametric abscess.

George E. Gask.

SWELLING IN THE ILIAC FOSSA (LEFT). For the general method of examination, compare SWELLING IN THE ILIAC FOSSA (RIGHT), p. 827.

I. SWELLINGS CONNECTED WITH STRUCTURES NORMALLY PRESENT IN THE LEFT ILIAC FOSSA.

The Sigmoid Flexure cannot be felt normally. It becomes palpable as a cylindrical swelling if distended with feces ; or if it is thickened by chronic ulcerative colitis or in congenital dilatation of the colon. An X-ray photograph after a bismuth or barium enema is an excellent method of demonstrating any mechanical blockage (*Figs. 643, 644*).

Carcinoma of the Sigmoid. Next to the rectum the sigmoid colon is the most common seat of cancer in the bowel. If of the scirrhus or ring type no lump may be felt, and the condition may not be discovered until intestinal obstruction has supervened. When infiltrating the bowel widely, and especially when the tumour is undergoing colloid degeneration, a swelling forms which is most evident on bimanual examination after the bowels have been cleared well by enemata. If a lump can be felt in the sigmoid flexure of a middle-aged patient the strong probability is that it is a carcinoma, and whether there are other clinical signs or not the diagnosis should be made sure by actual inspection of the swelling

by means of the sigmoidoscope, or even through an abdominal incision. It may be simulated by subacute inflammatory changes around an acquired pouch or diverticulum of the colon (*diverticulitis*): this sometimes subsides by itself, and the course of the case serves to exclude carcinoma: more often the symptoms call for operation, and the diagnosis is made by laparotomy.

Enlarged Lymphatic Glands. The glands forming a chain round the external iliac vessels may be swollen as the result of pyogenic infection which has spread up through the femoral lymphatics, or from secondary deposit of some malignant growth starting either in the leg, the external genitals, or the pelvis. The enlargement is seldom very great: the source of infection is usually obvious.

Aneurysm of the External Iliac Artery is very rare. It is recognized at once by its expansile pulsations.

2. SWELLINGS CONNECTED WITH STRUCTURES NOT NORMALLY PRESENT IN THE LEFT ILIAC FOSSA.

These may be: Swellings coming down from above, extending upwards from the pelvis, or pushing forward from behind.

Swellings coming down from above.

The *spleen*, if much enlarged, may reach

Fig. 641. Skiergram taken after the administration of a barium enema showing the site of a carcinoma of the sigmoid colon. The enema tube is still in the rectum; the rectum itself and the pelvic colon are distended with the barium, but the latter could not be made to ascend beyond the point, marked by an arrow, at which the cancer is obstructing the bowel. (By Dr. W. H. Colclough.)

Fig. 642. Skiergram showing the site of a stenosing carcinoma of the lower end of the descending colon. The limits of the carcinoma are indicated by the narrow isthmus of barium shadow between the two arrows. A barium meal had been given, and the barium that had been given by the mouth had reached the upper limit of the constricting constriction when a barium enema was administered; the latter extended up to the lower limit of the constriction, and the skiergram was then obtained. (By Dr. W. H. Colclough.)

even as far as the left iliac fossa. It is recognized by its rounded margin, and the notch on the inner edge. (See **SPLEEN, ENLARGEMENT OF THE**, p. 774.) A *kidney*, if freely movable, may be displaced as far as the pelvis: on rare occasions it becomes fixed there by inflammation.

For swellings extending up from the pelvis and those pushing forwards from behind, see the article below on **SWELLING IN THE ILIAC FOSSA (RIGHT)**. *George E. Gask.*

SWELLING IN THE ILIAC FOSSA (RIGHT). It is not always easy to say whether there is or is not a definite swelling in the right iliac fossa, for it may be only small and deep, or be masked by abdominal rigidity or fat. In all cases a careful inspection of the

abdomen is first to be made, the patient lying on the back with the whole of the abdomen and the lower thorax exposed. Most mistakes result from want of a complete examination, which cannot be made through a tiny gap in the clothes. Before even touching the abdomen, much may be made out by the use of the eyes, and the points to observe are : (1) The presence or absence of an obvious tumour ; (2) Whether the abdominal muscles move freely ; (3) The conformation, etc., of the tumour, should one be present, and whether it moves on respiration ; (4) Distention of the surface veins.

Palpation is then to be employed, and this method will go a long way to elucidate the complaint, for it will be recognized at once whether there is a well-defined swelling, such as a carcinoma of the cæcum or a low right kidney ; or an indefinite swelling, such as is common in appendicitis. Distention with wind or an accumulation of faeces may cause a considerable swelling of the cæcum ; doubt as to these may be cleared up by administering an enema. If the swelling persists, the questions that arise are : is it connected with one of the structures normally present in the right iliac fossa, especially the cæcum or the appendix : is it springing from the bone : is it arising from some organ invading this space, for instance the uterus or its appendages, the right ovary, or the bladder : or from some structure displaced downwards such as the gall-bladder, stomach, or right kidney ?

1. SWELLINGS CONNECTED WITH STRUCTURES NORMALLY PRESENT IN THE RIGHT ILIAC FOSSA.

The Appendix. *Appendicitis* is so common that it is put first. Most well-marked attacks of appendicitis are associated at some period with a swelling, though in the acutest and gravest forms it may be absent. The appendix itself, even if swollen and thickened, can rarely be felt by palpating the abdomen, and the swelling is due to paralytic distention of the cæcum, local œdema, or the formation of an abscess. The chief indications of appendicitis are : pain, tenderness, local rigidity, and swelling in the right iliac fossa, associated with a furred tongue, vomiting, constipation, an increase of the pulse-rate, and a rise of temperature. Usually there is also diminished muscular movement in the lower part, or it may be over the whole, of the abdomen. Any movement is painful, and in order to relax the tension the patient lies with the right leg drawn up. A rectal examination should be made, for a bulging abscess may be felt by this route. Micturition is frequently abnormal, with a tendency to be either painful or unduly frequent. A leucocyte count is of service, for in almost every case of definite appendicitis the number of white cells is increased.

Tuberculosis of the Cæcum or of the Lymphatic Glands in the neighbourhood of the Cæcum. This is not nearly so common as appendicitis, but is not so rare as is often imagined, and when it does occur it is frequently mistaken for appendicitis (*Fig. 449*, p. 562) : it may be only after the abdomen has been opened that the mistake is discovered. The glands become enlarged and painful, and there may be some local peritonitis over them which makes the diagnosis difficult. Usually there is some other tuberculous focus about patient, especially in the lungs, which should be examined with particular care, the x-rays and sputum analysis not being omitted. If doubt exists recourse may be had to a diagnostic injection of Koch's old tuberculin, or to von Pirquet's test.

Actinomycosis starting in the cæcum and appendix is another inflammatory condition which may cause a swelling and give the signs of a chronic abscess. The diagnosis can only be made with certainty by an incision and the finding in the pus of the characteristic yellowish granules (occasionally black—the gunpowder variety), and the recognition under the microscope that these granules are formed of a Gram-staining streptothrix (*Fig. 610*, p. 779).

Carcinoma of the Cæcum gives rise to a swelling which occasions few symptoms unless the passage of faeces is affected and intestinal obstruction results. It is important, however, from the point of view of treatment that an early diagnosis be made. The presence of a non-inflammatory swelling of long standing in the right iliac fossa, with a history of wasting, is very suggestive of a carcinoma, and early recourse should be had to the only sure diagnostic method, namely, laparotomy. Very rarely is there passage of blood or mucus by the bowel to help one.

Intussusception usually occurs in children, especially during the latter half of the

first year of life, and its presence is indicated by vomiting, constipation, the passage of blood and mucus by the rectum, and by bouts of spasmodic drawing up of the legs and crying from the colicky abdominal pains. The intussuscepted portion may be palpable, and in some cases it lies in the right iliac fossa, though more frequently in the right hypochondrium or elsewhere in the abdomen. Chronic intussusception is met with in adults, causing abdominal pains and a swelling which generally baffles diagnosis until laparotomy is performed; it is commonly mistaken for an enlarged kidney or for a carcinoma of the colon, or for appendicitis or diverticulitis.

Aneurysm of an Iliac Artery is very rare, but it is generally easy of diagnosis by reason of the expansile pulsation of the tumour.

2. SWELLINGS CONNECTED WITH STRUCTURES NOT NORMALLY PRESENT IN THE RIGHT ILIAC FOSSA.

These may be: Swellings coming down from above, swellings extending upwards from the pelvis, or swellings pushing forward from behind.

Swellings coming down from above. The *liver*, or an enlarged or abnormal lobe of the liver (Riedel's lobe (p. 461) is sometimes deceptive. The facts that there are few symptoms, that the mass moves on respiration and is continuous with the liver, and that there is no intervening area of resonance between it and the liver, should assist the diagnosis; but cases are not infrequently mistaken for enlargement of the gall-bladder. A *suppurating gall-bladder* has been opened in the right iliac fossa under the mistaken diagnosis of appendix abscess, for there is often no jaundice in these cases. Laparotomy may be the only means of certain diagnosis.

The *kidney*, if unduly movable, may be displaced and come to lie in the right iliac fossa. It is recognized by its shape and free mobility. A tumour of the kidney or a large hydro- or pyo-nephrosis may also invade the upper part of this fossa.

Carcinoma of the stomach with extreme distention of the stomach. It is a surprising fact that the stomach may be so distended as to enable the pylorus to lie in the right iliac fossa. The history of copious vomiting, the wasting, the distention of the stomach, and examination with the X rays after the administration of bismuth make the diagnosis easy.

Swellings extending upwards from the pelvis, and attached to the uterus and its appendages, can usually be felt dipping into the pelvis: vaginal and rectal examinations will assist the diagnosis; and there are symptoms, such as disturbances of menstruation, indicating their nature. Such swellings might be a large *fibroid of the uterus*, a laterally placed *ovarian cyst*, *pregnancy*, an *abscess* extending from the broad ligament, or a *pouch of a bladder* distended from obstruction to the urethra.

It happens not infrequently that there may be difficulty in determining between an inflamed appendix and an enlarged and tender ovary, particularly when the attacks of pain are coincident with the menstrual periods. These generally turn out to be due to the appendix, though both may be implicated, the appendix having become adherent to the ovary or tube.

Pyosalpinx is easily confused with appendix abscess: the fact that it is associated with vaginal discharge, or is subsequent to parturition, puts one on the right track. Vaginal examination is essential in these cases: evidence of bilateral pelvic swelling is against appendicular trouble and in favour of pyosalpinx, for the latter generally affects both sides.

Swellings pushing forward from behind. These may be solid, such as *sarcoma* or *chondroma* of the pelvic bones. Here the tumour will be immovable apart from the pelvis, and a skiagram makes the condition clear. If the swelling is fluid it may depend on *suppurative osteomyelitis* of the ilium; or on a *tuberculous* affection of the ilium, either primary, or secondary to hip or sacro-iliac joint disease; or on *tuberculosis, necrosis, or suppuration of the lumbar vertebrae*.

If the swelling cannot be attributed to any of the causes mentioned above, it is to be remembered that a wandering organ, such as a spleen or kidney, may find its way into the right iliac fossa. Rarities such as hydatid cysts of the peritoneal cavity are met with so seldom that they merit no more than mention.

George E. Gask.

SWELLING, INGUINAL. A variety of swellings may appear in the groin and be very difficult to differentiate. The following are some of the most important : (1) *Enlarged glands* : (a) inguinal ; (b) femoral ; (c) iliac. (2) *Abscess, acute or chronic*. (3) *Hernia* : (a) inguinal ; (b) femoral ; (c) obturator. (4) *Retained testicle*. (5) *Hydrocele*. (6) *Tumours of the cord or round ligament*. (7) *Aneurysm and other vascular swellings*. (8) *New growths*. (9) *Distended psoas bursa and other cysts*.

1. **Enlarged Glands.**—There are three chief groups of glands in the groin. The most commonly affected are the *inguinal*, which lie in the subcutaneous tissues about Poupart's ligament and drain the external genitals, the anus, the umbilicus, the lower parts of the abdomen and back, the buttock, and the upper third of the thigh ; the *femoral* glands, which are below the saphenous opening and drain the lower limb below the upper third of the thigh, though the lymphatic drainage is somewhat erratic, so that a sore toe may sometimes induce enlargement of an inguinal gland only without enlarging the femoral group at all ; and the *iliac* glands deeply placed in the iliac fossa draining the inguinal and femoral set, and consequently often enlarging secondarily to these, though they also communicate freely with the other abdominal lymphatics and may become infected from them. Enlarged glands in the groin are nearly always multiple, and usually subcutaneous, so that they are easy to recognize as glands ; but a solitary one adherent to the saphenous opening may be almost impossible to distinguish from an irreducible omental femoral hernia or a hydrocele of a hernia sac.

The iliac glands just above Poupart's ligament are more difficult to palpate, because they lie deep to the abdominal muscles, but their enlargement is generally secondary to disease of the superficial glands, and this often gives the key to the diagnosis of an obscure swelling in this region.

Some Causes of Enlargement of the Groin Glands. (a) Mechanical or chemical irritation ; (b) Septic infection, for instance from genital sores or from sores on the toes or legs ; (c) Tubercle ; (d) Syphilis ; (e) Other specific diseases, such as rubella and bubonic plague ; (f) Lymphadenoma ; (g) Lymphatic leukaemia ; (h) Malignant diseases—secondary carcinoma, secondary or primary sarcoma ; (i) Filariasis.

a. The glands become slightly enlarged and tender as a result of the *mechanical irritation* of a truss, and more frequently the *bites of parasites* such as the *Pediculus pubis*. The glands generally remain movable, and they rarely suppurate.

b. *Septic infection* may follow insect bites ; but more commonly a septic sore or recent scar can be discovered upon examination of the area drained by the glands. Septic glands either soon subside, ceasing to be tender after the removal of the source of infection, or they enlarge rapidly, become adherent, and suppurate within one to four weeks of their first enlargement.

c. This, and the amount of inflammation of the skin over them, distinguishes septic from *tuberculous* glands, which do not suppurate for some months, and then with but little inflammatory reaction. Epitheliomatous glands may suppurate, and often ulcerate towards the end.

d. The true *syphilitic gland* is hard, movable, and only moderately enlarged, and the existence of the indurated chancre usually makes the diagnosis easy. The *Spirochæta pallida* may be detected, or Wassermann's serum test may be positive, though a negative reaction is not conclusive. An apparently soft sore (septic) may later become hard and definitely syphilitic ; therefore suppuration of a bubo does not disprove syphilitic infection. Instances of mixed infection by sepsis and syphilis are common.

f. In *lymphadenoma* the groin glands are rarely affected alone, and the smooth, soft enlargement of many glands without signs of inflammation, associated with increasing anæmia and intermittent pyrexia (*Fig. 566*, p. 708), makes the diagnosis fairly easy. The spleen may be affected at the same time.

g. Blood examination will give pathognomonic results in cases of *lymphatic leukaemia* (p. 33) and *filariasis* (p. 36).

h. *Malignant disease* of the groin glands is nearly always epitheliomatous, secondary to a primary epithelioma of the skin or mucous membrane in the area drained by the glands. The primary growth, especially at the anus, may be small, and the patient may be unaware of its existence. The other main points in distinguishing epitheliomatous glands are their exceeding hardness ; their progressive but slow growth ; their early

adhesion to the deep fascia and skin; the amount of pain to which they give rise without signs of inflammation. Late in the disease they may suppurate, ulcerate, or slough, with severe hæmorrhage. Intra-abdominal carcinoma, especially of the ovary or colon, sometimes causes enlargement of the inguinal glands.

Sarcoma of the groin glands is rare; it may be primary or secondary. Usually these are not the only glands affected. They grow with great rapidity and remain smooth and fairly soft until they attain a great size, when they may fungate through the skin. They are distinguished from lymphadenoma by their very rapid growth. Melanotic growths of the skin give rise to rapidly growing smooth glands whose pigment may be visible through the skin. The primary growth or ulceration in connection with the skin, particularly of a toe or a wart, may not show pigmentation, and its serious import may thus be overlooked. The urine may give a positive reaction for melanin or melaninogen (p. 905).

i. Filariasis: see (g) above.

2. Abscess.

a. Acute abscess has only one common cause, namely, suppuration of the glands, and a search must always be made for a primary source of infection, especially about the genitals or on the foot or in connection with a toe. A hernia may occasionally suppurate, and an appendicular abscess may point just above Poupart's ligament; but there is then a history of the characteristic symptoms of appendicitis, and the pus when released has the suggestive smell of the products of the *Bacillus coli communis*. Tuberculous and epitheliomatous glands may suppurate as the result of secondary pyogenic infection.

b. Chronic abscess here may be due to caries of the sacro-iliac joint or to hip disease, or it may arise from tuberculosis of the superficial or deep glands, or be the result of a psoas abscess due to caries of the spine, distinguished by fluctuation from the loin to the groin, often bilateral, above and below Poupart's ligament, external to the femoral vessels; there are also some tenderness and rigidity, and often deformity, of the lumbar or lumbodorsal spine. Iliac abscess does not extend up into the loin, and is placed farther out than psoas abscess; moreover, there may be pain and tenderness over the sacro-iliac joint, and a limping gait. In hip disease, especially in children, the floor of the acetabulum may give way, and an abscess may thus enter the true pelvis, whence it may ascend and become palpable above Poupart's ligament; the diagnosis of the cause is afforded by the signs of hip disease. Radiographic examination may reveal caries of the spine, sacro-iliac, or hip joint, but the absence of demonstrable radiographic changes does not always exclude caries. The exploring needle withdraws the characteristic contents of a tuberculous abscess, which are sterile on cultivation, but may infect a guinea-pig with tubercle; when a good-sized exploring needle repeatedly fails to find pus the swelling is probably a *lipoma*, which may resemble a psoas abscess very closely. A lipoma here is rare in children, and does not give rise to symptoms of spinal disease.

3. Hernia. In examining swellings in the groin hernia must always be considered. Three chief varieties occur here: inguinal, femoral, and rarely obturator hernia. A hernia gives an impulse on coughing, but so do psoas abscess, psoas bursa, and a saphena varix. All these may also be reducible like a hernia. A psoas abscess presenting below Poupart's ligament has been mistaken for a femoral hernia; but it is distinguished by its position—external instead of internal to the femoral vessels. Moreover, it is dull on percussion, whereas a hernia is resonant except when it contains omentum alone. Psoas bursa is also placed outside the vessels. A saphena varix has often been mistaken for femoral hernia; but it can be distinguished from the latter easily because it returns after complete reduction, even though the finger is kept pressed against the femoral canal. It is not always easy to distinguish the three herniæ which occur in the groin, but close attention to the following points usually leads to a correct diagnosis. An inguinal hernia is both seen and felt to be *above* the fold of the groin and *above* Poupart's ligament; whereas a femoral hernia is seen and felt to be *below* the fold of the groin and *below* Poupart's ligament. When a femoral hernia becomes very large and loculated it generally extends upwards and inwards over Poupart's ligament; still, the bulk of it remains below the fold of the groin in the upper and inner part of the thigh. An inguinal hernia often extends into the scrotum or labium; a femoral hernia never does this. The neck of an inguino-scrotal hernia is above and internal to the spine of the pubis, whereas the neck of a femoral hernia is below and external to this bony prominence. Inguinal hernia is most easily reduced by pressure

directed upwards, backwards, and outwards, whereas a large femoral hernia is reduced most easily by pressure directed at first backwards and downwards, and then directly upwards. In difficult cases it is a good plan to reduce the hernia, then to get the patient to stand up while the surgeon makes firm pressure over the internal ring and asks the patient to cough : a femoral hernia may then come down, but not an inguinal. Similarly, pressure can be made on the femoral canal ; this prevents the descent of a femoral hernia, so that if the swelling now returns it is inguinal. In this connection it should be noted that femoral hernia is rare in males, and in all females under maturity. The prevalent belief that femoral hernia is more common than inguinal in grown-up women is wrong, inguinal being more common at all ages and in both sexes. It is excessively difficult to differentiate between an irreducible femoral hernia containing omentum and an enlarged gland at the saphenous opening or in the femoral canal. A hydrocele of a hernial sac gives rise to the same difficulty, and sometimes an exploration becomes necessary on account of the danger of overlooking femoral hernia, and the risk of strangulation.

The diagnosis between femoral and obturator hernia is not very difficult ; it is far commoner to overlook an obturator hernia altogether. When an external swelling is caused by an obturator hernia it is placed farther inwards, and it is more vague than is a femoral hernia. Moreover, there is pain shooting along the inner side of the thigh, and generally the signs and symptoms of strangulation. Further, a tender swelling can be felt at the obturator foramen upon vaginal or rectal examination.

The two chief varieties of inguinal hernia, the oblique and the direct, are usually distinguished quite easily. Direct hernia is rare, and it is more globular than either indirect or oblique hernia : the spermatic cord is antero-external to it, and postero-internal to the ordinary oblique hernia. Direct hernia is placed a little farther in and higher up than the oblique. It is generally reduced more easily, but it returns again with striking abruptness when the patient coughs. It rarely travels into the scrotum, and it is uncommon before the age of thirty. There is often a history of sudden onset after some violent straining effort.

4. Retained Testicle. The most important points in the diagnosis of this condition are the absence of the organ from its proper place, and the presence of a swelling about the inguinal canal. Occasionally, the testicle may be maldescended, or after leaving the external ring it may have found its way into the upper and inner part of the thigh where it simulates a femoral hernia, or into the perineum. The swelling in the groin may give the characteristic testicular sensation, or the condition may be associated with attacks of pain which have been mistaken for appendicitis or intestinal colic. It is practically always accompanied by actual or potential hernia into the tunica vaginalis, which is in direct communication with the abdominal cavity.

5. Hydrocele. The neck of the sac of either a femoral or an inguinal hernia may become obstructed, and a hydrocele of the sac may then develop. This may become inflamed and give rise to considerable difficulty in diagnosis. Strangulated or irreducible omental hernia may be simulated, and sometimes an exploration is the only way of settling the diagnosis. It is more easily distinguished from strangulated hernia containing bowel, because it is dull on percussion, and the bowels are not obstructed. An encysted hydrocele of the cord occupying the inguinal canal is sometimes difficult to distinguish from inguinal hernia ; but it is not completely reducible, and it is dull on percussion. It is not granular to the touch like an omental hernia, and it can even be shown, with some difficulty, to be translucent. Like a hernia, it gives an impulse on coughing.

6. Tumours of the Cord or Round Ligament.—The only common tumours of these structures are (*a*) Lipoma and (*b*) Fibromyoma of the round ligament. The former is so soft and displaceable that it gives an impulse on coughing, and is often mistaken for an omental hernia, especially in stout patients. The latter is hard and smooth, somewhat simulating the ovary or a thick-walled hydrocele of the canal of Nuck, for either of which it may be mistaken, a certain diagnosis being possible only by exploration.

7. Aneurysm and other Vascular Swellings. Aneurysm of the external iliac artery may be mistaken for a vascular sarcoma arising from the pelvis. It can generally be recognized by the classical signs of aneurysm, such as expansile pulsation, bruit, weakening and delay of the corresponding femoral pulse, and marked reduction of the size of the

swelling as a result of pressure on the common iliac artery. Saphenous varix has been referred to above.

8. New Growths. Sarcoma of the pelvic bones or of the soft parts in this neighbourhood is hardly altered in size by pressure upon the common iliac artery, nor does it give such a loud bruit or the *expansile* pulsation which are characteristic of aneurysm. The X rays may give evidence which is valuable in distinguishing aneurysm from sarcoma. A lipoma deeply placed in the groin is very apt to be mistaken for a cold abscess, but an exploring needle fails to withdraw pus.

9. Distended Psoas Bursa may give rise to pulsation communicated from the external iliac artery. On careful examination it can be distinguished by the absence of the classical signs of aneurysm already mentioned, by its translucency, and by its irreducibility. There may also be signs of osteo-arthritis of the hip-joint. *R. P. Rowlands.*

SWELLING, INGUINO-SCROTAL.—The most important swellings which occupy both the inguinal and scrotal regions are: (1) *Hernia*; (2) *Varicocele*; (3) *New growth*; (4) *Hydrocele*; (5) *Lymphangioma*.

Hernia is by far the most common, and when it is reducible there is very little difficulty in the diagnosis. It gives the characteristic impulse on coughing, is resonant on percussion, and when it contains bowel it gurgles on reduction. When it contains omentum only the diagnosis is more difficult. To distinguish it from a *varicocele* it is only necessary to reduce the swelling and then to place the finger firmly upon the inguinal canal: a varicocele returns in a few seconds, but a hernia does not. Moreover, an omental hernia has a granular feel which distinguishes it from varicocele. An irreducible omental hernia is distinguished from varicocele by its irreducibility; but it may be confused with a rare condition, *lymphangioma of the cord*. An irreducible hernia may be confused with encysted hydrocele of the cord. When a hernia contains bowel its resonance distinguishes it: but when it contains omentum there is more difficulty. An *encysted hydrocele* or a *hydrocele of a hernial sac* is more even and elastic than an omental hernia, which is usually nodular. Moreover, it may be possible to show that a hydrocele is translucent. This help is not available when the cyst is deep or contains blood which it occasionally does as the result of injury or strangulation of the omentum at the neck of the hernial sac. A *strangulated hernia* is distinguished from an inflamed hydrocele by the greater severity of the vomiting and other constitutional symptoms, and the completeness of constipation. Moreover, a strangulated hernia containing bowel is resonant on percussion. Strangulated omentum may be difficult to distinguish from an inflamed hydrocele or a hydrocele of a hernial sac, especially as either of these may complicate it. In such cases an exploration is the final appeal. Two or more varieties of inguino-scrotal swellings may co-exist: for instance, it is common to overlook a hernia which may complicate a varicocele, and this is especially true when the hernia contains only omentum: again, it is common for a hydrocele of the tunica vaginalis or of the lower part of the cord to complicate an ordinary omental hernia. In such a case, a part of the swelling may be reducible, and, unless the patient is examined in the upright position, the upper part of the hernia may fail to appear during the examination; the bowel may be reducible, while the omentum, being adherent, is not reducible, and may be mistaken for an encysted hydrocele of the cord. It is important in all these cases to examine for translucency.

Growths of the testicle invading the inguinal region are, as a rule, diagnosed easily, because of the history and the observed course of the disease, and the general condition of the patient at the later stages. *Growth of the retained testis* may give rise to more difficulty: it may be confounded at first with hydrocele of the tunica vaginalis, hydrocele of the hernial sac, or omental hernia, unless care be taken to ascertain if both the testicles are present in the scrotum. *Torsion of a retained testicle* with strangulation of its vessels has sometimes given rise to inguinal or inguino-scrotal swelling which has simulated strangulated hernia; but although there may be much abdominal pain and local tenderness, vomiting is rarely so severe as in strangulated hernia, and the bowels are not really obstructed. Retained testicle is dull on percussion, and thus distinguished from strangulated hernia containing bowel; but not from strangulation of omentum in a hernia.

Oblique inguinal hernia is the only common one to reach the scrotum. It may be acquired or congenital. In about one-tenth of the congenital herniæ the bowel and the

testicle are in the same peritoneal sac; in the majority of both congenital and acquired herniae the two sacs are distinct, the testicle lying below the hernia. Most inguinal herniae descend into congenital or pre-formed sacs, and this is especially true of herniae appearing apparently for the first time in young adults. In such cases, on careful inquiry, it may be found that a hernia existed and was apparently cured by a truss, in infancy; or it may be learned that the hernia reached the scrotum on its first descent, whereas acquired inguinal hernia develops gradually as the result of straining in men past middle age. The swelling appears at first only in the inguinal region, it then increases in size, and extends into the scrotum only after some months or years. Very rarely a direct hernia may reach the scrotum; it is distinguished from oblique hernia by the fact that the cord is antero-external to it, instead of postero-internal, as in an oblique hernia. It may be possible in some cases to identify the contents of a hernia. Attention has been drawn above to the method of distinguishing the bowel from the omentum. Sometimes the appendix can be felt distinctly, especially in right-sided hernia. Occasionally the bladder may be identified, as in Astley Cooper's classical case; when the patient has apparently emptied the bladder the surgeon reduces the hernia, and the patient is immediately able to pass more water.

R. P. Roelands.

SWELLING OF THE JAW, LOWER. Swelling of the lower jaw may sometimes be mistaken for, or masked by, swelling of the cellular tissues in front of it. The real site of the swelling is first to be ascertained by opening the mouth and running the finger along the outer and inner borders of the mandible and comparing the two sides.

There are many causes for enlargement, and they may be subdivided under the following headings:

(1) *Injury*. (2) *Inflammatory affections*. (3) *Tumours*: Innocent fibroma, osteoma, and odontoma; Malignant sarcoma and epithelioma. (4) *Acromegaly*. (5) *Leontiasis ossea*.

1. Injury.—A *hematoma* or traumatic *periostitis* may follow a blow. If the injury has caused a *fracture*, the abnormal mobility of the fragments, the irregularity of the line of the teeth and arch of the jaw, the laceration of the gums, serve to indicate the injury. The nearer the line of fracture is to the symphysis the more marked is the mobility, and diagnosis is only difficult when the fracture is of the ascending ramus and underneath the masseter muscle. A skiagram may then be needed. Fracture of the mandible is commonly compound, and therefore is often complicated by septic infection. Later, *callus* will form a tumour which might be mistaken for one of some other kind until the course of the case has been watched.

2. Inflammatory Affections.—*Alveolar Abscess* is a common swelling, associated with toothache. An ordinary gumboil forms on the outer side of the gum, and is quite superficial. A more troublesome form of abscess is that which develops at the root of a tooth, which, generally carious, may yet appear healthy on the surface. Pus usually points between the gum and the cheek, but it may travel a long way between the bone and the mucous membrane, and point on the cheek, in the submaxillary region, or on the chin. As in the case of injury, *periostitis* extending up under the muscle may be difficult to diagnose, and it is sometimes mistaken for parotitis. In the early stages the only sign is toothache, but as suppuration becomes established there are also pain, swelling of the gums, furred tongue, trismus, enlargement of the upper cervical lymphatic glands, raised temperature. The presence of a septic tooth indicates the diagnosis.

Necrosis of the Jaw, often preceded by an acute periosteal abscess, may follow injury, alveolar abscess, syphilis, or mercurial or phosphorus poisoning, and in rare cases acute exanthemata or typhoid fever. In many cases it may be impossible to say whether the bone is necrosed or not, for the signs are much the same as in suppuration in connection with alveolar abscess. It can only be diagnosed for certain if a piece of loose bone can be felt with a probe or seen by the aid of a skiagram. Its presence may be inferred by the long continuance and profuseness of the discharge.

Syphilitic Disease of the lower jaw is rare, and if present will not usually be confined to the jaw. If there is doubt, a Wassermann's reaction will be of service.

Actinomycosis. A long-standing and obstinate suppuration about the lower jaw with cellulitis of the neck and formation of sinuses in the skin (*Fig. 645*) should

lead to the suspicion of the nature of the trouble. In the beginning it gives rise to inflammatory changes which simulate alveolar abscess, and the similarity is increased by the presence of carious teeth, through which the fungus is believed to gain access to the jaw. In the pus, the small yellow granules are to be sought for, and the Gram-staining mycelium on microscopical examination (*Fig. 610*, p. 779).

3. Tumours. In many cases there will be no difficulty in deciding whether a swelling is inflammatory or a new growth. In the early stages, however, and an early diagnosis in the case of malignant disease is of extreme importance, there may be grave doubt. Therefore all possibility of inflammatory mischief should be excluded by a careful, thorough examination of the mouth and teeth for any source of infection, and for this purpose it is frequently advisable to invite the co-operation of a dentist.

*Fig. 615. Actinomycosis of the neck and jaw.
(From Boche's 'Die Chirurgie des Kopfes', Julius Springer, Berlin.)*

Innocent tumours are osteoma and fibroma (more commonly called a fibrous epulis). *Osteoma* is rare, very slow-growing, well defined, bony hard, not usually attaining a very large size. A not uncommon place to find it is at the angle of the jaw, projecting into the mouth. It may be bilateral. *Fibrous epulis* is common, soft, composed of fibrous tissue, and covered by the mucous membrane of the gum. It arises in connection with the root of a decayed tooth, and if not treated may attain a sufficient size to cause displacement of the teeth or even distortion of the arch of the jaw. Sarcomata may start in this manner; therefore all such tumours should be submitted to microscopical examination before a definite diagnosis or prognosis is given.

Malignant tumours are *primary*—sarcomata—and *secondary*—epitheliomata, which start in the gum or on the floor of the mouth and invade the jaw by direct extension.

The diagnosis of *sarcoma* may be quite easy, or attended by the greatest difficulty. They occur at any age, even in young infants. They may be of rapid growth, associated with constitutional changes which simulate inflammatory conditions before a large size has been attained, or they may be of such slow development as to be confounded with

innocent growths. The necessity of early diagnosis cannot be urged too strongly, for it is on this that successful treatment depends. Seeing that a growth may be mistaken for a swelling due to suppuration, examination should first be directed towards seeing if any of the ordinary signs of inflammation are present, and whether there is an obvious source of infection. The history of the duration of the illness may be of great service, and also the nature of the swelling itself. Is it hard or soft, is the bone expanded, are tissues round the bone infiltrated, are the glands enlarged? Exercising the greatest care, diagnosis may still be difficult, and much service is rendered by a skiagram, with the aid of which one may determine whether the swelling is really bony, or in the case of periosteal sarcoma if the bone has been eaten into. If the diagnosis can be settled by no other means a piece of the growth should be removed for microscopical examination even if the tumour is bony and a chisel and mallet are required.

Epithelioma better termed squamous-celled carcinoma is a very insidious and dangerous form of growth, and in its early stages very apt to be overlooked. It may start as a small ulceration of the gum about a decayed tooth, and so be mistaken for a simple ulcer, and it may not be until a large tumour has formed that the condition is recognized, when most valuable time will have been lost from the point of view of treatment. The diagnosis will be made by careful examination,

Fig. 646. Skiagram showing a dental cyst of the right mandible, connected with a crowned second bicuspid tooth. (By Dr. J. H. Mather.)

Fig. 648. Skiagram showing a follicular odontoma or dentigerous cyst of the left superior maxilla, in the form of a thin-walled cyst with a tooth within it. (By Dr. J. H. Mather.)

Fig. 647. Skiagram from a case of myeloid sarcoma of the lower jaw. The diagnosis was confirmed by histological examination. (By Dr. J. H. Mather.)

and noting that the ulcerated gum is hard and indurated and does not heal when the decayed tooth is removed. The name 'boring epithelioma' has been well applied to this condition. To make the diagnosis sure a piece from the edge of the ulcer should be removed for histological examination at the earliest moment that suspicion is aroused as to its malignancy. An epithelioma may also spread from the tongue or floor of the mouth and cause a swelling involving the jaw. The diagnosis here is obvious.

Tumours of the Teeth, Odontomata, may arise from any portion of the dental tissue, either from the tooth germ or from the fully-formed tooth. Clinically they are innocent, and commoner in young people. The method of diagnosis is to examine the teeth and find out if any of them are missing or abnormally arranged. It is easy to distinguish them from a periosteal sarcoma, but confusion may arise between them and a very slow-growing endosteal or myeloid sarcoma. A skiagram will generally reveal the true state of affairs (Figs. 646-648), for any abnormality or misplacement of the teeth is clearly shown.

It is well to remember the existence of these tumours, for unnecessarily severe operations have often been performed in ignorance.

Two diseases in which the mandible becomes enlarged, but in which the swelling is not confined to the one bone, and is only one of the manifestations of the complaint, remain to be mentioned :

4. **Acromegaly.** The lower jaw is often enlarged conspicuously in this disease, becoming prominent and massive (*Fig.* 250, p. 293). There is hypertrophy of the whole bone rather than a swelling in it. The other bones of the face are enlarged, the superciliary ridges are exaggerated, and the general effect of the disease is to give the patient the appearance of a dull, coarse-featured person. In addition, the hands and feet become much enlarged ; also, in the late stages of this very chronic illness, headache and muscular debility become prominent symptoms, and owing to swelling of the pituitary body (see *Fig.* 310, p. 379), bilateral temporal hemianopia is to be expected (*Figs.* 305, 306, pp. 377, 378).

5. **Leontiasis Ossea** is the name given to a rare disease in which hyperostoses of the facial and cranial bones are the distinguishing features. It is not likely to be confounded with any of the above-mentioned swellings, except perhaps acromegaly, from which it is distinguished by the absence of changes in the hands and feet. *George E. Gask.*

SWELLING OF THE JAW, UPPER. The remarks made in the article on SWELLING OF THE JAW, LOWER (p. 834), apply equally to swellings in the upper jaw. Tumours arising in the antrum of Highmore merit special mention, however, for many cause no pain or discomfort until the late stages. Though innocent tumours may start in the antrum, the commonest are sarcoma and endothelioma. Rapid growth, bulging into and invasion of surrounding fossæ, pain, discharge of blood and pus from one nostril, and invasion of the overlying skin, are momentous indications of malignant disease. In the case, though, of slow-growing tumours and in the early stages, differentiation between innocent growths and suppuration is extremely difficult. Transillumination (see PAIN IN THE JAW, UPPER, p. 567) is to be employed (*Fig.* 191, p. 226), also puncture of the antrum, and if necessary exploration and histological examination of the parts removed. The antrum of Highmore is one of the sites in which endothelioma occurs as a primary new growth. *George E. Gask.*

SWELLING OF THE LEGS. (See ŒDEMA, p. 511.)

SWELLING, MAMMARY. *Method of Examination.*—The clothes should be removed to the waist, so that a clear view of both breasts, the thorax, axillæ, and supraclavicular fossæ may be obtained. Both breasts should then be looked at to see whether there is any obvious enlargement or abnormality such as redness of the skin, dilatation of veins, tumour, or ulcer. Next, palpation is to be employed, using the flat of the hand and not the tips of the fingers : the surgeon should place himself in a convenient position behind the patient, using the right hand to examine the right breast and the left hand the left. The axillary fossæ should also be palpated carefully, it being remembered that the lymphatic glands affected in diseases of the breast lie on the surface of the thorax and not round the axillary vessels. (See SWELLING, AXILLARY, p. 816.) In cases of suspected cancer the examination must not be concluded without investigation of the supraclavicular fossæ for fullness or enlargement of glands, and of the thorax and liver for signs of secondary growths.

Swelling in Pregnancy and Lactation is normal and physiological. Both breasts are enlarged equally, and feel tense and nodular. The superficial veins are usually prominent, and on gentle squeezing a few drops of milk are discharged from the nipple.

True Hypertrophy of one breast is rare. It may be found in nursemaids who have put children to the breast. The enlargement in the majority of so-called cases of hypertrophy is really due to the presence of one or more fibro-adenomata.

Acute Mastitis occurs usually during lactation, occasionally during pregnancy, and is most often due to infection with pyogenic organisms which have gained entrance through cracks in the nipple. At the beginning of the illness there is shivering, followed by fever and a feeling of weight and pain in the breast ; the pain soon becomes very acute ; in the early stages the swelling is limited to one part of the breast, which feels more resistant

than normal: the skin is not reddened at first, nor are the lymphatic glands enlarged. Pressure over the swelling may cause extrusion of a drop of pus from the nipple, and this is distinguished from milk by its viscosity and yellow colour. Later, fluctuation may become evident, and, as the inflammation approaches the skin, this becomes red and oedematous, and ultimately an abscess may point and burst through it: at the same time other foci of suppuration form, until the breast may be nothing but a bag of pus. The presence of fever and the intense tenderness of one portion of the breast are sufficient to distinguish acute mastitis from the physiological engorgement.

It is not uncommon to find a small *alveolar abscess*, the size of a hazel-nut, in virgins.

Soon after birth and at puberty, a diffuse enlargement may occur in both sexes, and a small quantity of milk may be secreted. If the breasts are handled or squeezed this congestive condition may pass into true inflammation and suppuration.

Chronic Mastitis may attack numerous lobes of the breast, so that the whole organ has a granular feel (chronic lobular mastitis), or the inflammation may be confined to one segment and form an inflammatory swelling of considerable size, difficult to distinguish from carcinoma until microscopical examination has been made. The attention of the patient is usually first called to the breast by the presence of vague pains and tenderness. If the lump is picked up with the fingers it is easily palpable, but if pressed back against the chest wall the induration is much less distinct than in carcinoma or fibro-adenoma. The swelling is elastic, and its outline quite diffuse, more so than in the case of carcinoma. The axillary glands may or may not be enlarged: if they are, they are generally numerous, not so hard as in cancer, and are met with at an earlier period in the disease. The opposite breast is very liable to be diseased in a similar manner. In cancer the tumour is densely hard, and at an early period adhesions form so that the skin puckers on attempting to move it over the swelling. A further difficulty arises from the fact that a cyst may form in connection with chronic mastitis. If this is lax, fluctuation may be detected, but it is usually so tense that it feels hard and solid. This again may be mistaken for a carcinoma or a fibro-adenoma. Where there is the least doubt as to the nature of the swelling and any possibility of the presence of a carcinoma the right course is to make an exploratory incision and cut microscopic sections from the suspected area.

Multiple Cystic Disease of the Breast. This condition may follow on chronic lobular mastitis. One breast sometimes both becomes filled with cysts, some microscopic, others as large as walnuts, with all intermediate sizes, so that the organ has a bossy appearance. The whole organ is often painful, the pain radiating from the breast and shooting down the arm. There are epithelial changes in the lining membrane of the cysts, and some authorities think that these are precursory stages in the formation of a cancer.

Cysts, unless in connection with chronic mastitis or fibro-adenomata, are rare. A simple serous cyst is described, due to lymphatic obstruction. *Galactocoele*, a cyst containing milk, is formed by dilatation of one of the larger lacteals owing to obstruction: galactocoeles occur only during lactation: they form movable, fluctuating swellings, and on pressure milk can be squeezed out of the nipple.

Tuberculosis of the Breast is not so uncommon as might be supposed, and a certain number of cases of chronic mastitis and chronic abscess are really tuberculous. The disease is insidious, starting as a painless irregular swelling, the periphery of which is hard and the centre soft. Later, the skin becomes reddened, and an abscess forms which may burst and leave a sinus. It differs from an acute abscess in that the duration is much longer, there is little or no pain or fever, and the pus, if examined, reveals no organisms on culture unless there has been secondary infection: direct examination of stained films of the pus may show tubercle bacilli. The facts that the history is a long one, that the swelling or the edges of it are hard, and that the axillary glands are enlarged, render this condition liable to be confounded with carcinoma, of the ordinary form, or one in which suppuration has occurred. The various clinical pathological tests for tuberculous disease may be applied, but the best method is to cut into the swelling and remove a portion of the wall for histological examination.

Chronic Submammary Abscess causes a projection forward of the whole breast: it is due to tuberculosis of the underlying ribs, or in rare instances to post-typhoidal peristitis which may have remained latent. The diagnosis is made by opening the abscess and examining the pus from it bacteriologically.

Innocent Tumours.— *Pure fibromata, lipomata, and enchondromata* are of rare occurrence, and merely call for mention. *Fibro-adenoma* is the only common innocent tumour, and though there are many pathological varieties, and some contain cysts and some intra-cystic growths, for the purposes of this article all may be classed under one heading. A *fibro-adenoma* is an encapsulated tumour, generally single, sometimes multiple, varying from the size of a nut to that of an orange. Because it is encapsulated, the surrounding tissues are not infiltrated: therefore, if superficial, the outline is clearly defined, and the mass is freely movable under the skin, over the pectoral muscle, and, most important of all, in the breast substance. The axillary glands are not enlarged. The tumour causes no pain, and is usually discovered accidentally. Generally it occurs in women between the ages of twenty and thirty. After attaining a certain size it remains more or less stationary, unless it is cystic, when it may go on growing as the result of dilatation of the cysts by fluid. The diagnosis is generally easy, but if the breast is fat and the tumour deep-seated, it may not always be quite easy to distinguish a fibro-adenoma from an early carcinoma without operation and microscopical examination. A fibro-adenoma is elastic rather than hard like a carcinoma. From chronic mastitis it is distinguished by being less intimately associated with the breast than is the case with the inflammatory nodules, and by its sharper definition. No definite diagnosis or prognosis should be given, however, until the tumour has been removed and a pathological report on its character received.

Malignant Tumours of the breast are nearly always primary: sarcoma is rare, carcinoma common: and the latter is the most important tumour that affects the breast. It is essentially a disease of the female, only about one per cent of the cases occurring in males: most patients have been married, and are between the ages of thirty-five and sixty. In advanced cases the disease is obvious: the tumour is large and hard, fixed to and often fungating through the skin: the axillary glands are enlarged and hard, and the patient is often cachectic. What is sought for is a diagnosis in the early stages, while the patient still looks and feels in perfect health, before secondary deposits arise in the axillary glands, and while successful treatment is still possible. Too much insistence cannot be laid on this. Usually the patient feels no pain, but discovers a lump in the breast accidentally during ablutions: therefore its duration must generally be a matter of doubt. Clinically, it is felt as a small tumour which, unless the patient is very fat, can be palpated easily with the flat of the hand. Its chief characteristic is that its outline is not sharply defined, and that it is hard—stony hard. In the very early stage the tumour is freely movable over the pectoral muscles and under the skin, but it is not so movable in the breast substance as is a fibro-adenoma. Very soon bands of fibrous tissue that connect the breast with the skin become involved, and by their contraction prevent free movement of the skin over the swelling, and cause dimpling and puckering. If the tumour is situated anywhere near the centre of the breast, milk-ducts become involved in the growth, and as they contract cause retraction of the nipple. If a nipple, previously well formed, becomes retracted, this is a very important sign, though it is to be remembered that nipples are often permanently retracted. Many cancerous tumours, even when extensive infiltration has occurred, cause shrinkage, so that the affected breast may appear smaller than the healthy one, and in the atrophic form the gland may almost disappear. In the ordinary form (scirrhous) it will be rare to find any discharge from the nipple: a blood-stained discharge often indicates a duct carcinoma. (See DISCHARGE FROM THE NIPPLE, p. 227.) After the disease has lasted six months the axillary glands are usually enlarged and hard, the first affected being those running along the lower border of the pectoralis minor. Too much attention must not be given to the absence of palpable glands, because, first, it is hoped that the diagnosis may be made before they are enlarged: and secondly, if the patient is at all fat, it is exceedingly easy to overlook them. Attention is to be centred on the lump itself. Its stony hardness may alone be sufficient ground on which to base a diagnosis. The two main conditions which have to be distinguished from an early carcinoma are fibro-adenoma and chronic mastitis. In the former, the swelling is well defined, elastic, and freely movable: in the latter, a tumour cannot be felt distinctly with the flat of the hand, it is soft, the whole breast is often nodular, and the other breast may give a similar feeling.

The difficulties in diagnosis are great and the sources of error numerous: none of the

swellings may be typical; they may be obscured by the obesity of the patient; a fluid swelling may be so tense as to simulate a solid one. The course to adopt, whenever the slightest doubt arises, is to incise the swelling and submit a portion to microscopical examination. Owing to the vital importance of avoiding mistakes in this connection there is a growing feeling among surgeons that all tumours of the breast, whatever the belief as to their character, should be removed, or at least cut into, so that their true histological constitution may be ascertained early and with accuracy.

Sarcoma of the breast is rare. It generally occurs in women under the age of thirty. In the early stage it is not distinguishable easily from a fibro-adenoma, particularly one which is enlarging rapidly on account of a cyst or intracystic growth. It is soft, grows quickly, infiltrates the tissues, and forms a large fungating tumour. It disseminates rapidly, both via the lymphatics and by the blood-stream. *George E. Gask.*

SWELLING, PELVIC.—There are so many swellings which may rise up out of the pelvis into the abdomen, and also which may appear to be pelvic when they are really primarily abdominal, that a list in tabulated form may be of value:

Bladder.—Simple distention. New growth.

Vagina.—Hæmatocolpos.

Uterus.—Pregnancy: normal or abnormal, or associated with tumours of the uterus or ovary.

New growths: Fibromyoma. Adenomyoma. Sarcoma. Carcinoma.
Chorion-epithelioma.

Hæmatometra.

Ovary.—Cysts. Solid new growths.

Fallopian Tubes.—Hydrosalpinx

Carcinoma

Pyosalpinx

Tubal gestation

Salpingo-oöphoritis

Progressive extra-uterine gestation.

New growths

Pelvic Peritoneum.—Encysted peritoneal fluid

Hæmatocele due to extra-uterine gestation

Hæmatocele due to hæmorrhage from a corpus luteum

Pelvic abscess

Hydatid cysts

Ascites

Retroperitoneal lipoma.

Pelvic Cellular Tissue.—Cellulitis. Pelvic hæmatoma.

Appendix Vermiformis.—Abscess

Appendicitis with pregnancy.

Pelvic Bones.—New growths.

Omentum.—New growths. Cysts.

Phantom Tumours.

Pancreatic Cysts.

Kidney.—Tumours. Hydronephrosis. Pyonephrosis.

Gall-bladder.—Distention.

Spleen.—Enlargement.

Urachus.—Cyst.

It is obvious that many of these lesions are not pelvic at all; but they are included in the list, because they are liable to be mistaken for pelvic tumours. Thus *pancreatic, renal, splenic, and gall-bladder tumours* may reach the pelvic brim, but the history ought to show that they have grown down from above, not up from below. Further, *renal tumours* may be associated with urinary changes, or absence of urinary secretion on the affected side, as detected by the cystoscope. *Splenic enlargements* may be associated with blood-changes, and *gall-bladder distention* with icterus. *Pancreatic cysts* are the least likely to be mistaken for pelvic swellings, but they have been difficult to distinguish from ovarian tumours with long pedicles.

Naturally, the commonest difficulty which arises in the diagnosis of pelvic swellings is to differentiate between the *distended bladder, pregnant uterus, ovarian cyst, and uterine fibromyoma*, and the commonest mistakes are made between these swellings. The

distended bladder is clearly the easiest to dispose of, because the passage of a catheter will settle the question; and yet the neglect of this simple procedure has led to more than one abdomen being opened.

The history is of value in differentiating the other swellings, for amenorrhœa is the rule in pregnancy, menorrhagia in fibromyoma, and no change in menstruation in ovarian tumours. These assumptions are correct in almost 99 out of every 100 cases, but exceptions do exist. The cardinal point in diagnosis is not to think of the possible fallacies until the common rule has been considered thoroughly. Normal menstruation during pregnancy is almost unknown, but it is believed that menstruation is possible up to the third month. This is physiologically unsound, for menstruation represents the failure of the uterus to receive a fertilized ovum, and should not be even possible if conception does occur. That hæmorrhages occur during the early months of pregnancy is true; but in most cases these hæmorrhages represent threatened abortion, and not menstruation. Further, fibroids are associated with hæmorrhages. This is true in the case of interstitial or submucous growths; but there may be no disturbance of menstruation in subperitoneal fibroids. Ovarian tumours only disturb menstruation when they are double and destroy all ovarian tissue. As long as a small piece of ovarian tissue remains there is no reason why menstruation should not occur normally.

Palpation of these tumours may be fallacious, although there is no difficulty in distinguishing fetal parts when the fetus is big enough. In the early months the pregnant uterus may fluctuate like a cyst; a softened fibroid may do the same; whilst on the other hand a tense ovarian cyst may feel so hard as to be mistaken for a fibroid. Whilst the presence of the fetal heart is characteristic of pregnancy, its absence cannot be taken as evidence of a fibroid or of an ovarian tumour. It is not always possible to hear the fetal heart even in advanced pregnancy. If the pedicle of a tumour can be felt definitely attached to one uterine cornu it is strong presumptive evidence of an ovarian tumour. It is useful to pull down the uterus with a tenaculum, at the same time pushing up the tumour so as to make tense the pedicle, which might then be palpated by the vaginal touch. When small tumours are in question the first point which arises is: Can the tumour be separated from the uterus bimanually? If so, it can be neither a fibromyoma of the uterus nor a normal uterine pregnancy. This point can only be made out by careful bimanual examination, and undoubtedly may require considerable skill in some cases.

Early pregnancy in a retroverted uterus should not give rise to diagnostic difficulties if it be remembered that the soft, boggy fundus is felt through the posterior fornix, that the cervix looks down the vagina or forwards to the symphysis, and that the posterior mass is continuous with the cervix. If the retroverted uterus is associated with vesical distention the picture is usually clear enough. The history of constant dribbling of urine (distention with overflow), amenorrhœa, other signs of pregnancy, the presence of two tumours—one in front, tense and elastic, the other behind, soft and boggy—and, finally, the passage of a catheter, will settle the question. The diagnosis of solid ovarian tumours is not always possible, for the pedicle is often short, and the tumour is then so close to the uterus that the two cannot be separated. They are therefore likely to be mistaken for fibroids of the uterus. They do not often cause menorrhagia, however, and this may be remembered as a cardinal point.

Large tumours arising in the pelvis are not often difficult to differentiate from one another, bearing in mind that ovarian tumours, uterine fibroids, pregnancy, and ascites are the common conditions which are met with. In this connection, it cannot be repeated too often that amenorrhœa stands for pregnancy, and occasionally for ovarian tumours when double. Menorrhagia goes with uterine fibroids except in the case of subperitoneal tumours. Exceptions to these general statements are uncommon, and mistakes in diagnosis will occur but seldom if they are borne in mind. Ascites has to be differentiated from ovarian cysts, and occasionally from hydramnios. In general, ascites gives dullness in the flanks on percussion, with resonance over an area somewhere about the umbilicus, whilst ovarian cysts give dullness over the front of the abdomen, with resonant areas in the flanks and epigastric angle. When ascites exists along with ovarian tumours the free fluid may be so large in amount that the tumour cannot be felt; as a rule, however, it can be touched on dipping through the fluid. Ascites with an ovarian tumour does

not necessarily mean malignancy, but it may do so. Fibroma of the ovary, and simple ovarian cyst, with a twisted pedicle, will always be accompanied by some fluid.

When *pregnancy is associated with tumours*, the diagnosis may be of great difficulty. This does not lie in the recognition of the pregnancy: amenorrhœa, breast changes, fetal movements, and the fetal heart will usually make that clear enough; it lies in deciding the nature, or even the presence, of a tumour along with the pregnant uterus. In the early months, when the presence of two tumours can be demonstrated, the diagnosis is easier, but in the later months the great size of the abdomen, and the way in which the swellings merge into one another, may obscure the picture. The relation to the uterus, whether a part of it, or attached to it by a pedicle; the feel of the tumour, whether solid or cystic, soft or hard; and the previous history, will always be of assistance in making out the nature of the growth. Fibroids are extremely likely to soften and degenerate during pregnancy, so that they are liable to be mistaken for ovarian cysts.

In the case of *ovarian tumours*, it is often impossible to be sure of the exact nature of the growth, and this has to be decided microscopically after removal. It is, however, important to distinguish malignancy in growths of the ovary, and certain points will stand out in favour of this. Thus, fixation of the growth in the pelvis, obvious ascites, emaciation of the patient, and rapid growth in size of the abdomen, are points in favour of malignancy.

In the case of definitely *uterine tumours*, the diagnosis of malignant growths is not often difficult, but may have to be settled by microscopic examination of curetted fragments. Fibroids are only likely to be mistaken for malignant growths when they produce constant bleeding as a result of extrusion, infection, and sloughing. Rapid growth of a fibroid is more likely to be the result of degenerative changes, such as formation of cysts or necrobiosis, than to the development of a sarcoma or other malignant growth along with it.

With small tumours confined to the pelvis, or rising only a little above the brim, diagnosis is often a matter of extreme difficulty. In practice, however, *extra-uterine gestation* and its resulting blood-tumours stand out pre-eminently as swellings which must be recognized at once, if successful treatment is to be adopted. Before rupture or abortion has occurred a tubal gestation is essentially a small tumour in one postero-lateral corner of the pelvis, attached to the uterus, indefinite in consistence, and perhaps though not always—associated with amenorrhœa of short duration, and attacks of pain in the pelvis of an acute nature. Definite signs of pregnancy may be entirely wanting. It may be mistaken for a chronic salpingo-oöphoritis, a small cystic ovary, a small pedunculated fibroid, or a small ovarian dermoid. The differential diagnosis may be absolutely impossible; but attacks of pain unassociated with menstruation are not likely to occur in any of the latter conditions. The attacks of pain are usually the result of over-distention and stretching of the tube from hæmorrhage into its wall or lumen around the fertilized ovum. When tubal abortion has occurred, or tubal rupture, the signs of internal bleeding, accompanied by sudden pain and collapse, with hæmorrhage from the uterus, usually make an unmistakable picture. Hæmorrhage is more commonly severe and copious in tubal rupture than in tubal abortion. If the patient recovers from the initial bleeding the clinical picture may be that of a retro-uterine *hæmatocele*, or of a peritubal hæmatocele. In this form the uterus is pushed forwards and upwards against the symphysis pubis, and the mass of blood-clot can be felt posteriorly bulging the posterior fornix and also the anterior wall of the rectum. The tumour is usually partly resonant in front, because intestine adheres to it. Tubal abortion is most likely to be mistaken for an ordinary uterine abortion; but the presence of a mass on one side of the uterus, with a closed cervix, and the absence of uterine contractions or extrusion of any products of conception, should make the case clear.

Progressive extra-uterine gestation is a rare occurrence, and is the result of continued growth of an embryo after a partial separation from the tube as a result of rupture, or extrusion from the fimbriated end (abortion). The continued enlargement of a mass beside the uterus, with amenorrhœa and progressive signs of pregnancy, are the most characteristic points. The diagnosis, however, is difficult, because there is always some effused blood which is likely to obscure the outlines of the uterus, and make it appear to be a part of the pelvic mass.

The swellings due to *salpingo-oöphoritis* are usually quite easy to distinguish. They form fixed masses in the pelvis, seldom of any definite shape, but occasionally presenting the characteristic retort shape, with its narrow end near the uterus, which the tube assumes when distended with fluid. The history is usually that of an acute illness at some period, with pain in the pelvis, rise of temperature, and peritoneal irritation. It is preceded, as a rule, by uterine discharges and menorrhagia. This inflammatory disturbance in married women is associated with long periods of sterility, owing to the sealing up of the tubes. The diagnosis of suppuration with salpingo-oöphoritis is often difficult, but is always important, because correct treatment depends on it. Constant rises of temperature of the hectic type, leucocytosis, wasting, and daily sweating, are the usual accompaniments of suppuration here as elsewhere.

A large *pelvic abscess* may accompany salpingo-oöphoritis, or may occur alone without infection of the tubes, as we see occasionally in puerperal septic infections. When it does occur, it is of course peritoneal: it fixes the uterus in a central position, bulges into the posterior fornix and rectum, tends to rupture into the rectum, is acute in onset, and accompanied by signs of local peritonitis. It is likely to be confounded with *pelvic cellulitis*, in which the uterus is fixed in a laterally displaced position. This bulges one lateral fornix, tends to burrow along the round ligament to the groin, is slow in onset, chronic, and not accompanied by signs of local peritonitis. It always follows labour, whereas pelvic abscess of peritoneal origin may occur with salpingo-oöphoritis quite apart from pregnancy. Pelvic cellulitis never bears any relation to salpingo-oöphoritis.

Encysted peritoneal fluid, hydatid cysts, and retroperitoneal lipomata are generally diagnosed as ovarian cysts, and their true nature is only discovered at operation. There are no definite signs by which these conditions may be diagnosed, and as they all require operative treatment, post-operative diagnosis meets their requirements.

Distention of the vagina by menstrual fluid is not likely to be mistaken for anything else, if only on account of the absolute closure of the hymen which gives rise to it. Hematocolpos is practically the only central tumour met with between the rectum and the bladder reaching from the hymen to the pelvic brim. The uterus can usually be felt like a cork movable upon its upper extremity.

Urachal cysts occur in front of the uterus and in close relation to the bladder: but in spite of this they are usually mistaken for ovarian cysts. It is to be remembered, however, that ovarian cysts only get in front of and above the uterus when they are large. Urachal cysts rarely attain a large size.

Appendicitis with pregnancy occurs occasionally, and may be mistaken for such a condition as torsion of an ovarian pedicle. The swelling due to appendix inflammations is, however, in close relation to the anterior superior spine of the ilium, and apparently adherent to the iliac fossa. The lump is ill-defined, and rarely fluctuates unless there is a large abscess. The acute onset may be similar to that of torsion of an ovarian pedicle. There is usually a definite fluctuating tumour when an ovarian cyst is present, and some interval between it and the iliac crest can usually be felt.

Phantom tumours are due to diaphragmatic contraction, causing the abdominal wall to bulge. They are usually mistaken by patients for pregnancy, but are not accompanied by any of the signs of pregnancy. Amenorrhœa must be expected from this, however, because these cases usually occur about the menopause. Their true nature can usually be discovered by making the patient breathe normally, relaxing the diaphragm: but if any doubt exists, the protrusion will disappear under an anæsthetic.

Growths of the pelvic bones are very rare tumours, usually cartilaginous or sarcomatous. They are only likely to be mistaken for adherent inflammatory masses due to salpingo-oöphoritis. They will be found to be continuous with the bones forming the pelvis, and when growing from the sacrum may have the rectum in front of them: all other tumours have the rectum behind them. They may, however, bear no relation to the rectum at all if they occur on the right side of the pelvis. In most cases of this nature the uterus and adnexa can be palpated bimanually, and shown to be free from disease and unconnected with the mass. When complicated by the presence of a pregnant uterus their true nature may be very difficult to determine. Bearing in mind that they are absolutely fixed and continuous with the bones of the pelvis, the diagnosis ought not to be uncertain.

T. G. Stevens.

SWELLING, PERINEPHRIC. (See KIDNEY, ENLARGEMENT OF, p. 437.)

SWELLING, POPLITEAL.—Popliteal swellings may be divided into :

1. Fluid Swellings :—

Bursa		Baker's cyst	Varicose veins	Abscess	Aneurysm.
-------	--	--------------	----------------	---------	-----------

2. Solid Swellings not connected with Bone :—

Enlarged glands		Malignant tumours		Innocent tumours.
-----------------	--	-------------------	--	-------------------

3. Solid Swellings connected with Bone :—

Exostosis		Sarcoma	Periostitis		Separation of the epiphysis.
-----------	--	---------	-------------	--	------------------------------

1. FLUID SWELLINGS.

Bursa.—The bursa underneath the insertion of the semimembranosus muscle into the posterior aspect of the inner tuberosity of the tibia is often enlarged. When the leg is extended it stands out as a tense fluctuating swelling on the inner side of the popliteal space; on flexion it disappears completely. It may be found enlarged in young athletes and cause no symptoms whatever. On account of its frequent communication with the knee-joint it is often distended when that joint is the seat of osteo-arthritis, and the changes found in the synovial membrane of the knee are found also in the synovial membrane lining the bursa, for the two are continuous. When much fluid is present, fluctuation can be detected between the joint and the bursa. The cyst does not always communicate with the knee-joint, and it may not be reducible at all by pressure. It is enlarged occasionally in acute rheumatism in children, and may then be very tender; the swelling does not then disappear rapidly, as the joint pains do, on the administration of salicylates, but only gradually as acute rheumatic infection passes off.

The bursa under either of the two heads of the gastrocnemius muscle may be enlarged similarly, but this is rare.

Baker's Cyst occurs in connection with chronic inflammatory affections of the knee-joint; it may be formed by the extension of a chronic tuberculous abscess which spreads along a plane of fascia, and such an abscess may point in the popliteal space. The condition of the knee-joint will indicate the disease.

Varicose Veins are often present in the popliteal space; the diagnosis presents no difficulties, as the veins in the lower part of the leg will be varicose also.

Acute Abscess is recognized by the signs of acute inflammation; the skin is red and œdematous, the pulse and temperature are raised, and the swelling is very painful. The knee is kept flexed in order to minimize the tension of the part. The abscess may be caused by suppurating lymphatic glands or by suppurative periostitis or necrosis of the lower end of the femur. In the former case the abscess will be superficial, and in the latter deep to the popliteal vessels.

Aneurysm of the Popliteal Artery (*Fig. 649*) gives rise to an expansile pulsating tumour, the pulsation being synchronous with the heart's beat. Pressure on the femoral artery above will cause a diminution in size of the swelling and cessation of pulsation. The pulse at the ankle on the affected side may be smaller than that on the opposite, and delayed. If a stethoscope be placed over the swelling a distinct bruit can be heard. The complaint of the patient will probably be of pain, which may be referred down the leg if either popliteal nerve is pressed on, or in the site of the swelling if the bone is eroded. Varicose veins are almost always present also, on account of pressure on the popliteal vein. Owing to its pulsatile character an aneurysm is not often mistaken for anything else, but every swelling that pulsates is not an aneurysm. A soft vascular sarcoma growing from the end of the femur may be pulsatile, and over it a bruit may be heard, but the tumour is not as compressible as an aneurysm is, and the effects on the distal pulse are not so marked. A skiagram will usually settle the question at once. Distinction must also be drawn between a tumour that pulsates and a tumour to which pulsation is communicated. For instance, an abscess or a solid swelling lying over the popliteal artery may appear to pulsate, but the movement is heaving in character and not expansile. In the rare event of an

aneurysm having become filled with clot it might be taken for a solid tumour growing either from the soft parts or from the bone. Under this impression a leg has been amputated for sarcoma.

2. SOLID SWELLINGS NOT CONNECTED WITH BONE.

Enlarged Glands. It is not common to find the popliteal glands enlarged from any cause. It is possible that they may become infected with pyogenic organisms from a sore on the back of the leg.

Tumours are rare. They may be innocent, e.g., *lipoma*; or *sarcomatous*, starting in the connective tissue of the popliteal space, or attached to one of the muscles. The innocent tumours are of long history and well defined; the malignant, rapidly growing and infiltrating.

3. SOLID SWELLINGS CONNECTED WITH BONE.

In all cases of bony tumour a skiagram is of immense service and should always be obtained if possible.

Innocent Tumours. *Cancellous exostoses* may be found, generally in children and young adults, growing from the region of the epiphyseal cartilage of the femur (Fig. 633, p. 820). There may be others in other parts of the skeleton, and sometimes several members of the family are affected similarly. The swelling is of slow growth, well defined, and rarely gives any trouble. It is most often found at the inner side of the popliteal space. There is one thing that may be confounded with it, namely, *ossification of the insertion of a tendon or muscle*. The adductor longus muscle is the one most commonly affected (rider's bone).

Malignant Tumours are endosteal and periosteal sarcoma. *Central sarcoma* in its early stages resembles chronic osteitis and periostitis so closely that it may be impossible to come to a correct conclusion without the aid of a skiagram. With this help the difficulty vanishes, for a myeloid tumour is seen clearly as a well-defined tumour causing enlargement of the bone (Figs. 639-641, pp. 822, 823).

Periosteal sarcoma (compare Figs. 635, 636, p. 821) causes a general enlargement of the whole of the lower end of the femur or upper end of the tibia, not swelling in the popliteal space only. It is mentioned here because of its occasional confusion with periostitis and popliteal necrosis.

Periostitis. Popliteal necrosis with abscess formation may give rise to a big swelling. The signs of inflammation will usually be well marked and accompanied by constitutional symptoms and leucocytosis. Chronic periostitis, or chronic abscess of the bone, or central necrosis, may be extremely difficult to distinguish from a periosteal sarcoma. A skiagram

Fig. 639. Aneurysm of the popliteal artery.

should be taken, and if necessary an incision made down to the tumour for a piece to be removed for histological examination. (See SWELLING ON A BONE, p. 817.)

Separation of the Epiphysis. In the somewhat rare accident of separation of the lower epiphysis of the femur the lower fragment becomes displaced backwards, forms a prominence in the popliteal space, and presses on the vessels, sometimes to a dangerous extent.

George E. Gask.

SWELLING, PULSATILE. When a tumour can be felt pulsating, the first point to decide, if possible, is whether the pulsation is expansile or whether it is merely transmitted by a non-expansile tumour which is in direct contact with large pulsating vessels. The distinction is sometimes obvious, especially when the tumour has developed in a place where there are no particularly large blood-vessels to transmit pulsation, for instance in the foot, or in direct connection with a long bone at some spot not immediately adjacent to the main artery of the limb. The chief difficulty arises when the mass is either in the root of the neck or in the abdomen, and, to a less extent, when it is in the axilla, the inner aspect of the upper arm, in front of the elbow, in the groin, or in the popliteal space. Careful palpation is probably the best means of determining whether or not there is actual expansile pulsation: in the case of the abdomen it is important to examine the patient

not only when he lies on his back, but also in the knee-elbow posture, for sometimes a tumour which is in contact with the aorta in the former position falls away from it and ceases to transmit pulsation in the latter.

If it can be decided definitely that the tumour is itself pulsating, most probably it is either an *aneurysm* of an artery or else a very vascular growth, especially *osteosarcoma*. The existence of egg-shell crackling with pulsation in a tumour would suggest osteosarcoma, though it is conceivable that it might also be felt over an aneurysm that had eroded adjacent bones extensively. Aneurysm will be the probable diagnosis when the markedly pulsatile swelling occurs directly along the course of a known artery. Absence of pulsation does not, however, exclude aneurysm, for the latter may either be situated too deeply for the pulsation to be felt, or else the sac may be filled partly or wholly by organized or organizing clot.

Sometimes there may be doubt as to whether or not there is really pulsation when digital examination alone is relied upon: in such cases direct application of the ear to the part in such a way that the pinna is in uniform contact with the patient's skin will sometimes bring pulsation to the notice very clearly when

its amount, appreciable to the sensitive membrana tympani, is too slight for the hand to detect: this applies particularly to deep-seated intrathoracic aneurysms.

It must be remembered, on the other hand, that marked pulsation may suggest aneurysm without any being present, particularly at the root of the neck and in the abdomen (*Fig. 650*): a normal subclavian artery may sometimes seem to be abnormal, particularly if it is pushed forward or displaced by a mass below or behind it, for instance an accessory cervical rib. Undue pulsation of the abdominal aorta, especially in women, is also to be remembered as a possible source of erroneous diagnosis (see PULSATION, UNDEUE ABDOMINAL AORTIC, p. 662).

It should also be remembered that normal arteries cause violent pulsation in cases of marked aortic regurgitation, and in severe cases of exophthalmic goitre, in which the whole neck, including the enlarged thyroid gland, may be seen pulsating vigorously.

Fig. 650. Photograph illustrating the difficulty that may arise in diagnosing between abdominal aneurysm and carcinoma of the stomach. This patient had a large rounded epigastric tumour (demarcated by painting with ink before the photograph was taken) which pulsated forcibly, and the pulsation seemed to be expansile. Aneurysm of the aortic axis was diagnosed, but post-mortem examination revealed a large carcinoma of the stomach, and no aneurysm.

We need not here discuss in detail the differential diagnosis between one kind of aneurysm and another, though one might mention in particular the so-called cirroid aneurysm of the scalp (*Fig. 651*), which is rather a conglomeration of many abnormally dilated arteries in the form of an arterial naevus than a true aneurysm. Its position on the scalp will at once suggest the diagnosis.

Fig. 651.—Cirroid aneurysm.

A pulsatile orbital tumour will generally be due either to an osteosarcoma or to an arteriovenous aneurysmal communication between the internal carotid artery or its ophthalmic branch and the cavernous sinus. The presence of a loud bruit would be in favour of the latter.

It is important not to mistake for the ordinary pulsatile tumours those which may move synchronously with respiration, for instance hernia pulmonalis, hernia cerebri, and certain congenital abnormalities of the brain and spinal cord, such as meningomyelocele.

It is unlikely that a pulsatile liver will be mistaken for any other kind of pulsatile tumour. It occurs in cases of chronic failure of cardiac compensation, generally from mitral stenosis and tricuspid stenosis, with œdema of the legs, lividity, orthopnoea, and perhaps ascites. It is not, however, every liver, seemingly pulsatile, that really presents expansile pulsation: an impression of pulsation is often given by the movements transmitted directly to the liver by the labouring hypertrophied right heart.

Rarely the cardiac pulsations may be transmitted direct to fluid contained in a pleural cavity, so that the bulging intercostal spaces may pulsate synchronously with the radial artery and simulate some more serious pulsatile tumour. The history and the physical

signs, including displacement of the heart towards the opposite side, will generally indicate the correct diagnosis, though there may be some trepidation on the part of the operator who decides to insert the exploring needle into the pulsating swelling. *Herbert French.*

SWELLING OF THE SALIVARY GLANDS.

Epidemic Parotitis—Mumps is the commonest cause of swelling of the salivary glands; it is bilateral as a rule, and is discussed on p. 763.

Infective Parotitis is characterized by a sudden, acute, and generally unilateral enlargement, and is accompanied often by a rise of temperature or a rigor. It is not an uncommon complication in certain specific fevers, e.g., typhoid fever and pneumonia; and in surgical practice it may complicate any septic case, but especially abdominal, pelvic, and genito-urinary operations, puerperal infection, and pyæmia. Resolution usually occurs, but suppuration may ensue.

Salivary Calculus.—A calculus may be found in Stenson's duct, but is more common in the duct of the submaxillary gland. In the early stages such a calculus gives rise to sudden intermittent swelling of the affected gland at times when the stimulus of food gives rise to active secretion of saliva. As the result of long-standing distention and chronic inflammation the gland may become permanently swollen. The diagnosis of stone may

be made with the finger in the mouth, by pricking the calculus with a needle through the buccal mucous membrane, by passing a fine probe up the duct and feeling the grating on the stone, and by the use of the X rays (*Fig. 652*).

Parotid Tumours. Both innocent and malignant tumours arise in the parotid gland. The innocent tumours (fibromyxoma, endothelioma, teratoma) are encapsuled, grow slowly, press aside the rest of the parotid gland, shell out freely, and if removed do not recur. If left alone they may attain a large size in the course of years. The malignant tumours (sarcoma and carcinoma) grow rapidly, soon affecting the whole gland, extending deeply among the important structures behind the ramus of the jaw, and soon involving the facial nerve, causing facial palsy. The diagnosis has to be made from simple enlargements of the gland, and from enlargement of the pre-auricular lymphatic glands due to infection with pyogenic organisms, tubercle, or syphilis.

Tumours in the Submaxillary Salivary Gland are similar to but rarer than those which occur in the parotid gland.

Bilateral Salivary Swelling—Miculicz's Syndrome. This condition is characterized by a chronic bilateral swelling of the parotid, submaxillary, and sublingual salivary glands, together in many cases with simultaneous swelling of the lachrymal glands (*Fig. 46*, p. 34), and it is sometimes associated with enlargement of the spleen and lymphatic glands, and with changes in the blood. The general appearances of the face are those of persistent mumps, so to speak. The syndrome is not a disease in itself, but results most often from *lymphadenoma* or *lymphatic leukemia*; less often from some infection, including *tuberculosis* and secondary *syphilis*. A few cases have been attributed to *gout*. Each case should be investigated for any source of pyogenic infection from the mouth or gums, for syphilis by the Wassermann test, for leukemia by blood examination (p. 33), and for any evidence elsewhere of tuberculosis. *George E. Gask.*

Fig. 652.—Skigram of a large salivary calculus in the left submaxillary salivary gland. The arrow points to the calculus shadow. (*Fig. Dr. W. H. Caldwell.*)

SWELLING, SCROTAL. It is first essential to prove that the swelling is really limited to the scrotal region, and this is best done by grasping the root of the scrotum between the fingers and thumb, and thus ascertaining if the swelling does or does not extend into the inguinal region along the cord. Failure to take this obvious precaution has led to the tapping of a hernia, with disastrous results. True scrotal swellings may

arise in any of the following tissues : (1) Skin : (2) The various connective-tissue coverings of the testicle : (3) Tunica vaginalis : (4) Testicle : (5) Epididymis : (6) The lower end of the spermatic cord : (7) The urethra : (8) The bones of the pubic arch.

1. **Swellings affecting the Skin.** The nature of these is usually obvious. The only common ones are : Boils, soft sores and chancre, sebaceous cysts, warts, and epithelioma. The latter soon ulcerates, commonly occurs in sweeps, or in those who work in tar, tar-products, or petroleum, and the groin glands soon become enlarged.

2. **Swellings of the various Connective-tissue Coverings** are very rare, but occasionally a fibrosarcoma may occur. These swellings are movable upon the testicle. The symmetrical enlargement called *elephantiasis scroti* (Fig. 653), due to the *Filaria sanguinis hominis*, is limited to the tropics : though sometimes a similar state of scrotal distention and overgrowth results in this country from lymphatic obstruction due to pelvic cellulitis or to congenital abnormality. The enlarged scrotum resulting from acute generalized oedema in Bright's disease is seldom difficult to recognize : the penis and prepuce are generally distended by oedema at the same time as are the legs, loins, eyelids, and other parts : and the diagnosis is afforded by the albumin and tube-casts in the urine.

3. **The Tunica Vaginalis** may become distended with fluid the ordinary *vaginal hydrocele*. Except in late cases this is translucent, and thus distinguished from a hematocele of the same cavity, though a hydrocele with thick walls may fail to give translucency. When proved to be translucent, it has to be distinguished from encysted hydrocele of the epididymis and encysted hydrocele of the cord. Vaginal hydrocele occupies the lower part of the scrotum and *envelops the testicle*, which cannot be felt as a separate object. *Encysted hydrocele of the epididymis* is placed *behind and above the testicle*, from which it is distinct, although attached at the upper and posterior part. Moreover, this variety of hydrocele never attains a large size, rarely getting larger than a Tangerine orange. It is not tightly distended, but is usually flabby, and it contains a characteristic milky fluid in which cholesterol crystals (Fig. 263, p. 317) are present. *Encysted hydrocele of the cord* is placed *above the testicle*, which can be felt as a separate object. It rarely attains a large size, and is often elliptical in shape, extending upwards along the cord. All the hydroceles fluctuate. To test for this it is necessary to fix the swelling against some hard object. Bleeding may occur into any of them as a result of injury or constitutional disease. It is almost impossible to distinguish between an opaque hydrocele and a hematocele without tapping the swelling. In syphilitic disease, with irregular adhesion between the parietal and the visceral walls, a loculated hydrocele may occur.

4. **Swellings of the Body of the Testicle** may be inflammatory or neoplastic. Acute inflammatory swellings rarely attain a large size, and they are usually associated with enlargement of the epididymis, and occur as a part of acute epididymo-orchitis due to *urethritis*, *enlarged prostate*, or *pyelitis*, or to *mumps*, or as a *post-typhoidal* phenomenon. Chronic inflammatory swellings give rise to more difficulty. They are usually either *tuberculous* or *syphilitic*, or else due to *chronic torsion*. In the former disease, swelling of the epididymis is practically always primary and more advanced : but in infants the body of the testis becomes involved at a very early stage. The enlarged epididymis can be felt enveloping the posterior border and the upper and lower poles of the testicle. There is often a little hydrocele which may obscure the shape of the testicle. If there is adhesion, with perhaps an abscess or a sinus at the posterior and lower part of the scrotum, it is characteristic of suppurative disease of the epididymis, usually of a tuberculous nature. Moreover, in tuberculous disease the vas is thickened, usually in a nodular manner. It is important to examine all the palpable part of the vas, for sometimes the nodules are

Fig. 653. — Elephantiasis of the scrotum. (By F. H. B. Norris, F.R.C.S., Bengal, India.)

limited to the inguinal region. Von Pirquet's tuberculin reaction is a valuable aid if its limitations are remembered. In striking contrast with this, syphilitic enlargement of the testicle leaves the epididymis unaffected, and is limited to the testicle, which enlarges unevenly, often affecting the tunica albuginea and the tunica vaginalis in a nodular manner. The syphilitic testicle rarely attains three times the natural size. It is curiously devoid of pain. The testicular sensation is often lost, and there is little or no thickening of the cord. Its anterior surface is uneven and may become adherent to the coverings, which may later ulcerate, and ultimately give rise to a *hernia testis* on the front of the swelling. This contrasts with the postero-infero-lateral position of tuberculous sinus or *hernia testis*. *Chronic torsion of the testis* is generally the result of a blow, or of an injury in the saddle; the symptoms may be obscure until the testicle begins to swell. Operation is generally resorted to with the idea that the condition is tuberculous or malignant, and even then the diagnosis may be in doubt until microscopical examination of the organ has been made.

It is often difficult to distinguish syphilitic enlargement of the testicle from that due to *growth*; but a course of large doses of antisymphilitic remedies and the Wassermann reaction may settle the matter. Malignant new growth nearly always grows steadily, and being entirely within the tunica albuginea it maintains the shape and smooth surface of the testicle until it reaches a size much larger than that of a syphilitic testicle. Moreover, it causes much more pain, and usually some thickening of the cord, with later enlargement of the glands in the pelvis. In some cases the diagnosis between syphilitic testicle, growth, and hamatocele may be so difficult and so urgently necessary as to demand an exploration.

Malignant growths of the testicle can be divided into four varieties: (a) Carcinoma; (b) Sarcoma; (c) Embryoma; (d) Endothelioma.

Carcinoma is far more common than sarcoma, although the contrary has been believed for many years, owing to the fact that many carcinomatous growths with small alveoli have been wrongly labelled sarcoma. The average age of patients with carcinoma testis is 43, and of those with sarcoma testis 34. Sarcoma advances more rapidly and kills earlier than carcinoma. The former disseminates through the veins, whereas the latter travels along the lymphatics and infects the lumbar glands. Embryoma is, according to Nicholson, "the commonest new growth of the testicle, but it is often overlooked". It can be shown to contain structures derived from all the three blastodermic layers of the embryo. The average age at the time of operation is 29, the average known duration before operation is 5½ years. "Although not necessarily malignant, it may produce metastases composed of all the tissues of the primary growth, or one tissue may become actively malignant, in which case the deposits will be formed of that tissue alone." It may spread along the lymphatics or disseminate through the veins. Precise diagnosis depends on skilled histological examination.

5. The Epididymis may become enlarged as the result of: (a) Inflammation; (b) New growth; (c) Cystic degeneration.

a. Inflammatory swellings are characterized by being elongated in a vertical direction; by their relation to the testicle, which they overlap at its posterior border, and its upper and lower poles; and by being flattened from side to side so that the anteroposterior diameter is greatly increased. Inflammatory swellings may be: (i) Gonorrhœal; (ii) Septic, secondary to some other form of urethritis; (iii) Tuberculous.

The *gonorrhœal* variety is distinguished by its acuteness, great tenderness, the surrounding œdema, and the bacteriological examination of the urethral discharge. Its onset is usually between the second and tenth week. Occasionally a subacute form develops later, at any time during the course of gleet. This is very difficult to distinguish from the tuberculous variety. Most cases of tuberculous epididymitis end in suppuration, but the gonorrhœal variety very rarely breaks down.

The inflammation of the epididymis following other varieties of *urethritis* (such as ulceration near a stricture or due to impacted calculus, pyelitis, cystitis, prostatitis, instrumentation, or prostatectomy) is often sufficiently indicated by the history if care is taken to go into this thoroughly. The swelling following prostatectomy is apt to suppurate. Some of these can be mistaken easily for tuberculous disease.

Tuberculous epididymitis, as a rule, is more insidious and painless in its onset than

other forms of epididymitis; but early subacute or even acute attacks of inflammation may accompany this disease, and these often draw the patient's attention for the first time to a disease which has been going on insidiously for some months. It has frequently been said that tuberculous nodules are limited to the globus major, and that those left after gonorrhoeal urethritis are confined to the globus minor. It is more true to say that the latter are limited to the globus minor, whereas tuberculous disease may attack any part of the epididymis. Wherever the tuberculous disease starts, the inflammatory products soon spread through the thin fibrous capsule of the epididymis and then gravitate towards the postero-infero-lateral corner of the scrotum, where adhesion occurs, followed later by an abscess and a sinus. In the diagnosis of tuberculous from other forms of epididymitis the general state of health, and especially the presence or absence of other tuberculous lesions, are of great importance. Nodular thickening of the vas deferens and of the vesiculae seminales and prostate are also valuable signs when the disease is well advanced. The disease travels upwards along the vas, so that in its early and hopeful stages the upper part of the vas and the vesiculae seminales are not enlarged.

b. Primary new growth of the epididymis is excessively rare, so that it need not give rise to much concern in diagnosis; it will generally be regarded as tubercle until after operation and microscopical examination of the tissue excised.

c. Cystic disease of the epididymis may occur in the form of: (i) Solitary cysts (see above); (ii) Multiple cysts. The latter condition rarely occurs except in men past middle age, and is analogous to cystic degeneration of the breast. The condition is almost painless and harmless. These swellings are translucent.

6. Swellings of the Lower End of the Cord. The most important swelling of the lower part of the spermatic cord is *varicocele*. It is apt to be mistaken for omental hernia, but this mistake should never be made, because of the characteristic feel of the varicocele, and the reappearance of the swelling after it has been completely reduced and the finger is firmly pressed on the external abdominal ring.

7. Urethral Conditions. Occasionally a *peri-urethral abscess* may form a swelling in the scrotum. Tenderness, œdema, and fluctuation, together with the history and evidence of urethral disease, serve to make the diagnosis clear. *Primary epithelioma of the urethra* is distinguished by the great pain and urethral obstruction that it engenders.

8. Diseases of the Pubic Bones. Inflammatory products may travel into the scrotum from disease of the bones of the pubic arch, especially from the neighbourhood of the symphysis pubis. *Acute necrosis* of these bones is sufficiently indicated by the grave constitutional symptoms which always accompany it. *Caries* gives rise to more difficulty. The writer has known a case of tuberculous caries of the lower part of the symphysis pubis in which the inflammatory products gravitated backwards and to the left, so as to form a large firm swelling in the left half of the scrotum, where it gave rise to much difficulty in diagnosis, and was thought to be either a sarcoma arising from the fibrous covering of the crus penis, or possibly a gummatous mass in the same situation. Sufficient attention was not paid to the fact that the man had chronic phthisis.

George E. Gask.

SWELLING OF THE TONGUE is a condition the nature of which is generally obvious on inspection and palpation, if the history is taken into account at the same time, and many of the causes given in the following list need little detailed discussion:—

1. Causes of Acute Swelling of the Tongue:—

A bite or sting—wasp-sting for example
Injury, for instance by a fish-bone, or by
biting during an epileptic fit
Angina Ludovici
Corrosives or acute irritant applications
Acute œdema, secondary to:—

- a.* Inflammatory conditions within the mouth—Stomatitis (p. 661)
- b.* The effects of certain drugs, especially mercury

c. Erythema bullosum or pemphigus (p. 125)

d. Variola

e. Serum injections and other conditions liable to cause giant urticaria

f. Angioneurotic œdema

g. Raynaud's disease

Hæmorrhage into the substance of the tongue, as in scurvy, leukaemia, and other causes of purpura (p. 675).

2. Causes of Chronic or Persistent Swelling of the Tongue :

a. Where the swelling is general : -

Macroglossia
Cretinism

Myxedema
Mongolian idiocy

Acromegaly
Chronic dyspepsia.

b. Where the swelling is local or asymmetrical :

Irritation by a tooth-
plate or decayed
tooth
Epithelioma
Leukoplakia (chronic
superficial glossitis)

Gumma
Tuberculous infiltration
Actinomycosis
Calculus in a sublingual
salivary gland

Ranula
Suprahyoid cyst
Angioma
Sarcoma.

If the nature of the tongue enlargement is not obvious from the history and simple inspection and palpation—as will probably be the case when it is due to a *bite, sting, injury, corrosive or irritant* application, after the use of *mercury, serum*, or other drugs, *variola* or *pemphigus*—it may be so from the concomitant symptoms, as in the case of *cretinism* (p. 290), *acromegaly* (p. 293), *mongolian idiocy* (p. 236), or *myxedema* (p. 50). The swollen tongue of *dyspepsia* is seldom very large, though it may cause the patient discomfort at times from the sense of its being too big for the mouth: it is seldom difficult to recognize, from its pale flabby look and its marginal indentation by the teeth.

Simple *macroglossia* is rare: when it does occur the history is that it dates from youth or childhood, and the patient may otherwise be perfectly normal, unless he also has some other congenital peculiarity, such as *macrocheilia* (blubber-lips).

The chronic local lesions associated with swelling are in many cases associated with superficial ulceration, and the difficulties that may arise in distinguishing *simple, syphilitic*, and *epitheliomatous* trouble are discussed under **ULCERATION OF THE TONGUE** (p. 895). *Tuberculous* and *actinomycotic* lingual mischief are both rare, and on that very account may be mistaken for malignant or syphilitic disease unless bacteriological or histological methods of diagnosis are resorted to. *Ranula* and *sublingual salivary gland calculus* or *cyst* both cause swellings that are beneath the front part of the tongue rather than in its substance, generally bulging up one side of the floor of the mouth near the *frænum lingue*. A *ranula* is a distended mucous gland, and after enlarging slowly to the size of a chestnut perhaps, it often ceases to grow further: it does not fluctuate in its dimensions in relationship to meals, as a salivary gland swelling often does.

A *suprahyoid cyst* is situated in the root of the tongue posteriorly, where it arises from remains of the obsolete thyroglossal duct. It is seldom large: its nature may be suggested by its situation.

An *angioma* of the tongue is rare: sometimes, however, after remaining latent for years, it grows with rapidity and necessitates an operation. The diagnosis may be suggested by the colour of the tumour, but histological examination subsequent to removal may be required before one can be sure whether the tumour is a simple angioma, whether it has taken on the malignant characters of an angiosarcoma, or is a pure *sarcoma*.

Hæmorrhage in the substance of the tongue, with consequent great swelling of the organ and inability to use it for speaking or eating, may result from many of the different blood conditions that produce purpura. Only in very exceptional cases would such spontaneous bleeding be confined to the tongue, though conceivably this might be the first symptom in a case of acute lymphatic leucæmia, for example, or of purpura hæmorrhagica. Other hæmorrhages would follow, however, and indicate the need for blood-counts and other measures that are discussed under the heading of **PURPURA** (p. 675).

Raynaud's disease (p. 320) affects the fingers and toes more commonly than any other parts; it may, however, involve other distal tissues in a similar way, including the penis, the ears, the nose, and the tongue. In the latter it sometimes produces acute attacks of purple or almost black cyanosis, followed occasionally by local necrosis and subsequent scarring; acute swelling of the tongue may ensue when the paroxysm of vasoconstriction is passing off. It would be unique, however, for the tongue alone to be affected, and when the fingers and toes are attacked at the same time as the tongue the diagnosis is easy.

There remain for discussion acute oedema of the tongue due to *severe stomatitis*, *angio-neurotic oedema of the tongue*, and *angina Ludovici*. The latter is an acute, virulent, and

generally fatal condition, in which streptococci or other organisms attack the floor of the mouth and root of the tongue and without producing much pus, or even any at all, spread almost like wild-fire through the deeper structures of the mouth, throat, and neck, and cause extreme swelling of all the tissues in the neighbourhood. There is high fever, often a severe rigor, the patient is soon in a state of being hardly able to breathe, and extreme oedema of the glottis is apt to cause death from asphyxiation even when multiple incisions have been made into the brawny swollen parts. The condition is almost unmistakable; fortunately it is rare. It may be simulated by similar widespread oedema that results from infection of the deeper parts secondarily to one or other of the types of stomatitis discussed on p. 661; indeed, such stomatitis, when it has spread to the deeper tissues in this way, has virtually led to a secondary angina Ludovici; the latter name, however, is applied as a rule only to cases in which the acute overwhelming infection described above arises without any obvious preceding inflammation of the tongue or mouth.

Angioneurotic oedema of the tongue is rare, but it is of great importance because it is one of the purely functional conditions which may kill the patient. As a rule there is a history of similar attacks in other parts of the body previously (*Fig.* 407, p. 513), and other members of the family may be familiar with acute causeless swellings from personal experience, for it is a familial affection. Should it involve the tongue during a first attack, however, it would be mistaken for angina Ludovici very easily, especially as the patient may have pyrexia or a rigor notwithstanding the functional nature of the malady. Tracheotomy has been resorted to as the only means of saving the patient's life, and the diagnosis has only become clear when the oedema of the tongue and adjacent parts has subsided almost as rapidly as it came on, and the patient has had similar neurotic oedema, probably in other parts, on subsequent occasions.

Herbert French.

SWELLING, VULVAL. The differential diagnosis of vulval tumours must necessarily include not only true swellings of the vulva, but also swellings which appear at the vulva as a result of the displacement of other structures, such as occur in prolapse and cystocele, and in addition lesions like kraurosis vulvæ, which are not strictly swellings at all. The lesions of the vulva may be tabulated under various headings, as set forth in the following scheme:—

Inflammatory Lesions.

Simple vulvitis	Syphilis:	Furunculosis
Gonorrhœal vulvitis	Hunterian chancre	Leukoplakic vulvitis
Soft chancre	Condyloma	Kraurosis vulvæ
Papillomata	Tertiary lesions	Pseudo-elephantiasis
	Tuberculosis	Esthiomène.

Cystic Swellings.

Hydrocele of the canal of Nuck	Sebaceous cysts	Implantation cysts
	Mucous cysts	Dermoid cysts.

Blood Cysts.

Varicocele	Rupture of a varicose vein	Traumatic hæmatoma.
------------	----------------------------	---------------------

New Growths.

Caruncle	Neuroma	Squamous-celled carcinoma (epithelioma)
Fibroma	Fibromyoma of round ligament	Columnar-celled carcinoma
Lipoma	Endothelioma	Sarcomata of various kinds.
Angioma		

Herniæ.

Inguinal	Posterior labial	Perineal.
----------	------------------	-----------

Displacement.

Prolapse of urethral mucous membrane	Cystocele	Fibromyoma of the vaginal wall.
Prolapse of uterus	Inversion of the uterus	

Unclassified.—Simple anasarca.

Certain of these lesions stand out pre-eminently as presenting difficulties in diagnosis. The general principles by which solid tumours are distinguished from cystic, inflammatory swellings from new growths, or new growths from hernia, need not be insisted upon here. Perhaps the commonest difficulty which arises in practice is the diagnosis of gonorrhœal vulvitis from simple vulvitis, and also between the venereal soft chancre and the syphilitic condyloma, the latter differentiation being of much more practical importance than the former as far as the patient is concerned. In the acute stage of a *gonorrhœal vulvitis* there is a chance of recognizing the gonococcus in the discharge, if films made from it are suitably stained. Practically, *all* acute forms of vulvitis appear alike clinically, so that the recognition of the gonococcus becomes a matter of importance (see p. 231). In chronic gonorrhœal infections with vulval swelling, as a rule the organism cannot be found in the general vulval discharge, but might be found in the urethra or in the cervix. A gonorrhœal infection may be suspected if the patient gives a history of an acute onset, accompanied by scalding on micturition, and when there are redness of the orifices of Bartholin's glands, and much redness and swelling of the caruncula myrtiformes. Papilomata or warts of the vulva may occur also in chronic gonorrhœal infections, and there is no evidence of a reliable nature to show that they occur in any other kind of infection.

The *soft chancre*, from which Durey's bacillus may be recovered bacteriologically, may be mistaken for the *condyloma of secondary syphilis*, but as a rule this difficulty should not occur. The soft chancre is a typical punched-out ulcer with a somewhat red base and clean edges, discharging pus. The condyloma, on the other hand, is a raised, flat-topped excrescence, with sodden, epithelium-covered surface. Soft chancres are not very numerous, as a rule, and are generally limited to the vulva. Condylomata are numerous, and may occur all over the labia, around the anus, and even on the skin of the thighs and gluteal region. Condylomata are from the start, or very soon after, accompanied by a sore throat and a typical papular skin rash, for they are secondary syphilitic lesions. Soft chancres clear up with antiseptics; condylomata persist for long periods, but clear up in two or three weeks as a rule under mercurial treatment or salvarsan. It must not be forgotten that soft sores and condylomata may occur together in the same patient, in which case the diagnosis may be still more difficult.

Another practical differentiation which gives rise to anxiety is that between the *Hunterian chancre*, or primary syphilitic sore, and *squamous epithelioma* of the vulva. This is a question which is of vital importance to the patient if valuable time is not to be lost in the treatment of a malignant epithelioma. The two lesions look much alike at first; they form raised hard indurated masses in the skin, which may ulcerate quickly as a result of necrosis of the superficial portions. Both give rise to a thin watery discharge, and to enlarged glands in the inguinal region which do not suppurate at first, but may do so later in the case of an epithelioma. It must not be forgotten that a primary chancre is very seldom actually seen in women, whilst squamous epithelioma is directly visible. Of course the chancre will be followed in due course by secondary lesions, but it is not safe to wait for these to appear in a doubtful case. The only reasonable way to deal with such a case is to excise the doubtful swelling at once and submit it to microscope examination by an expert. A squamous epithelioma is detected easily in this manner in quite early stages, and does not in the least resemble a syphilitic lesion microscopically. The *Spirochata pallida* may be recognized in scrapings of a hard chancre by the Indian ink method, or when fixed and stained by Giemsa's or Levaditi's method. In sections, too, the spirochæte may be demonstrated, but it must be remembered that for this purpose the excised growth *must* be fixed in 5 per cent formalin solution. Wassermann's serum test may assist the diagnosis.

Tertiary syphilitic lesions are by no means common on the vulva. When they do occur they give rise to spreading ulceration with great destruction of tissue, and scarring in the older healed portions. Here, the only likely lesions to be mistaken are some forms of epithelioma, and tubercle. Obviously, in such conditions the only reliable method of diagnosis is by excision of parts of the lesion and microscopic examination of sections made from them. The disease known as *esthiomène* is probably a tertiary syphilitic affection.

Pseudo-elephantiasis of the vulva is usually a syphilitic affection of the labia minora, giving rise to great enlargement, with a rough and thickened appearance of the skin. It

could only be mistaken for real elephantiasis due to lymphatic obstruction by the *Filaria sanguinis hominis* (Fig. 603, p. 779), a disease which is practically never seen in this country.

Unilateral oedema of a labium minus is a fairly common condition, and is usually associated with an infected wound or with a primary syphilitic chancre. *Bilateral oedema* is almost always associated with general anasarca, the result of renal disease, pregnancy kidney, cardiac disease, or pressure upon pelvic veins. It is not likely to be mistaken for any other disease.

Leukoplakic vulvitis and *kraurosis vulvæ* have certainly been confounded with one another clinically, and also in the published descriptions of the lesions. In the former the labia majora and minora and the prepuce of the clitoris are affected, whilst the vestibule always escapes. In the latter the lesion affects the vestibule, the orifice of the vagina, and the labia minora. There is much greater contraction of the vaginal orifice in kraurosis. Leukoplakia often precedes a squamous epithelioma; kraurosis is said not to do so. Leukoplakia occurs at all ages, whilst kraurosis is a disease of post-menstrual life. Leukoplakic vulvitis appears as a white sodden hardening of the skin, with flattening and shrinkage of the labia. Kraurosis at first looks red and swollen, but later takes a yellowish tinge. Leukoplakia causes intense itching; kraurosis gives rise to great pain and tenderness, with a very severe form of dyspareunia.

Apart from a cyst developing in Bartholin's gland or duct, cystic swellings of the vulva are not common. A *Bartholinian cyst* is recognized by its position on one side of the vaginal entrance, distending the posterior part of the conjoined labia, and also within the hymeneal ring. As a rule the orifice of the gland can be seen on the inner side of the cyst. The contents of this form of cyst may be glairy mucoid fluid, or pus. In practice, a Bartholin cyst is not likely to be mistaken for anything else; but it is wise to remember that *posterior labial hernia* occurs in the same situation, and that new growths of the vulva may occur there as elsewhere. Bartholin cysts are always the result of infection, and as a rule a history of vulval inflammation can be obtained.

Varicocele of the vulva occurs practically only in connection with pregnancy, and is unmistakable. It has the same 'bag of worms' feel as has a varicocele in a man, and as the veins are close to the skin a bluish colour is always to be noted. It is attended by much aching pain, especially on standing. The veins are degenerate and liable to rupture as a result of labour or traumatism.

Hæmatoma of the vulva is recognized as a blue or violet-coloured swelling covered by tense shiny skin, and often spreading up into the pelvis by the side of the vagina. The history alone will often decide the nature of the swelling, but the appearance is quite typical as a rule. Hæmatoma of the vulva may occur apart from pregnancy, and then is always traumatic.

Urethral caruncle and *prolapse of the urethral mucous membrane* may be mistaken for one another. The former, however, is always a pedunculated or sessile new formation, invariably springing from the posterior wall of the urethral orifice. It bleeds readily, is often, but not always, exquisitely painful, and is usually the result of infection. Prolapse, on the other hand, appears as a raised projection with rounded margins, and with the urethral canal in the centre as a dimple. The prolapsed portion may not necessarily include the whole ring of the mucous membrane. It may give rise to pain, and being always more or less strangulated, it is prone to bleed, much in the same way as a caruncle. It occurs as a result of some straining effort, or may accompany pelvic floor prolapse; it is not the result of infection.

The differential diagnosis of the new growths of the vulva presents no points of difference from their diagnosis in other parts of the body. The only common benign tumour is the *pedunculated fibroma*, whilst *squamous carcinoma (epithelioma)* is the only malignant growth which occurs at all frequently.

If the general characters of a *hernia* are borne in mind, there should be no risk of overlooking or mistaking any of the varieties which occur in the vulva. The resonance on percussion if the hernia contains bowel, the reducibility of the contents, and the protrusion through a pre-existing opening, will usually suffice to distinguish hernia from other swellings. An obstructed or strangulated hernia is not so easy to recognize, but the accompanying acute symptoms and the previous history usually suffice to make the case clear.

Hydrocele of the canal of Nuck, an uncommon condition, may be mistaken for an inguinal hernia; but as a rule it is irreducible, definitely fluctuating and circumscribed, and has no obvious neck running into the inguinal canal. When the canal of Nuck has a patent peritoneal communication the swelling disappears as the patient lies down, but it is not reducible in the characteristic manner of a hernia. Such a condition is very rare.

The *displacements* included in the list above are all dealt with under the heading of PROLAPSE OF THE UTERUS (p. 657). T. G. Stevens.

SYNCOPE.—(See COMA, p. 153; FAINTING, p. 296.)

TACHE CÉRÉBRALE is the term used to denote that condition in which, after the finger has been drawn with moderate firmness across the patient's skin, the line along which it has passed becomes of a bright red colour from dilatation of the superficial arterioles and capillaries: the phenomenon develops within thirty seconds or a minute of

the finger stroke, and the red mark remains evident for two or three minutes or more. If letters or figures are marked out on the skin in this way, they appear as though they had been written in red, but the condition differs from factitious urticaria or dermatographia (*Fig. 654*) in that in the latter the central part of the local vasomotor reaction is white and the margins are red, as in a wheal, instead of the whole reaction being red as in tache cérébrale. It is seen characteristically in cases of tuberculous meningitis, but it is not pathognomonic, for not only is it sometimes absent in cases of the latter, but it is also present occasionally in a number of other different conditions, and sometimes in perfectly healthy people. All forms of meningitis may give

Fig. 654. Showing factitious urticaria, or dermatographia, in a man who seemed to be in perfect health. (*Cip Dr. Wilson.*)

rise to it, so that it is not even a means of distinguishing one type from another. A similar condition is observed sometimes in the later stages of severe febrile illnesses in general. Herbert French.

TACHYCARDIA, or abnormal rapidity of the heart's action, might, strictly speaking, be held to include every condition under which the pulse-rate is faster than the normal;

but by common consent it is restricted for clinical purposes to cases in which there is no pyrexia. Nearly all fevers produce undue rapidity of the heart's action, though some, such as typhoid fever, tuberculous meningitis, cerebral abscess, yellow fever, and influenza, do so to a much less extent than others. The rapid heart-action of fevers, however, does not generally come into one's mind when one uses the term tachycardia; indeed the latter is chiefly employed for conditions in which the pulse is rapid without there being anything which at first sight would seem to be a sufficient cause. Probably the best example of it is to be found in cases of pronounced *Graves' disease*. The following is a list including this and some other causes of tachycardia:—

Graves' disease or exophthalmic goitre
Paroxysmal tachycardia
Nervous excitement
Exertion, especially when the patient is out of training or anæmic
Tobacco heart
Mitral stenosis

Pneumogastric irritation by:—

Caseous glands; Thoracic aneurysms;
Mediastinal fibrosis; Thoracic new growth.

Pneumogastric 'neuritis' after:

Diphtheria, influenza, and other microbial affections.

Drugs:

Digitalis
Belladonna
Alcohol
Thyroid extract.

D.A.H. (disordered action of the heart), or soldier's heart.

The four classical symptoms of *Graves' disease* are : A staring appearance of the eyes, generally spoken of as exophthalmos, though there need be no actual protrusion of the eye-balls (*Fig. 504*, p. 643) ; moderate and almost symmetrical enlargement of the thyroid gland ; a pulse-rate between 120 and 180 per minute usually about 140 when the attack is moderately severe ; and extreme nervousness, with fine tremor of the outstretched fingers. When all these symptoms are present at the same time there can be little doubt as to the diagnosis, but very often some of them are absent, and it is possible for tachycardia to be the only symptom of the disease : indeed, in a patient, particularly a woman between twenty and forty years of age, a persistent pulse-rate of over 120 would arouse serious suspicion that the case was really one of Graves' disease, even if the other three classical signs were absent. There is a tendency nowadays to subdivide Graves' disease cases into two groups, viz. : (1) Parenchymatous goitre or true exophthalmic goitre ; (2) Toxic adenomatous goitre. The lines of distinction between these two groups are not absolutely clear ; but the more generalized the thyroid gland enlargement and the more pronounced the exophthalmos, the more does the case fall into Group 1 ; whilst on the contrary the more the goitre is asymmetrical or local, and the less classical the other symptoms, the more may the condition be classed as of toxic adenomatous type. In both there is tachycardia, but the pulse-rate is more steadily maintained week after week in cases in Group 1, whereas in cases in Group 2 the pulse-rate may vary day by day, tending always to be fast, but varying from 130 or more on some days to 90 or 100 on others in a way that is clinically different from what occurs in the well-defined parenchymatous exophthalmic goitre cases ; the exophthalmos, moreover, is more pronounced and more constant in cases of Group 1 than it is with cases of Group 2, in many of whom there is often but a recurrent stare with almost normal-looking eyes most of the time. It is difficult, however, to define exactly where the division comes between the two groups, and this even when basic metabolism researches have been carried out ; for although the basic metabolism figures may some day serve to distinguish one group from the other, the vagaries in each group are too variable for any constant deduction to be drawn from them.

Paroxysmal tachycardia should be distinguished at once from Graves' disease in which tachycardia alone has developed, by the fact that the tachycardia is not persistent, but recurs periodically with intervals of normal pulse-rate ; the patient is more often a woman than a man, and may have long periods of perfect health. Almost suddenly, the result sometimes of a fright or shock, sometimes without apparent cause, there is a sense of something being the matter in the precordial region, amounting as a rule to little more than a fluttering or palpitation, together with a feeling of faintness and lack of strength, and perhaps of numbness or of pins-and-needles in the extremities. When examined the patient may present no abnormality other than a pulse-rate of perhaps 160 or even 200 to the minute (*Fig. 655*). The attack may last a few minutes, or an hour or two, or for days, or more rarely for weeks ; it is apt to cease as suddenly as it began, and a similar attack is almost certain to recur after a longer or shorter interval the main symptom of the complaint being summarized by the title 'paroxysmal tachycardia'.

The very rapid heart action that may be produced by *nervousness, excitement*, or by some ordinary exertion such as coming rather rapidly upstairs when one is *out of training*, or when the patient is suffering from *anæmia*, or during *convalescence* after an illness, or after the over-use of *tobacco*, is a familiar phenomenon ; the tachycardia disappears rapidly when the patient rests, and the diagnosis is not as a rule difficult. If ordinary resting for a while does not cause the rate of the heart-beat to return nearly or quite to normal there may be doubt as to the diagnosis, unless the patient can be re-examined on another occasion ; if there is persistent tachycardia a suspicion of Graves' disease will be aroused, or there may have been acute overstrain of a weakened *fatty, fibroid, rheumatic, alcoholic, or syphilitic* myocardium, followed by long-continued tachycardia without bruit, but perhaps with *auricular fibrillation* ; electrocardiograms may be required before an exact diagnosis can be arrived at in many of these cases.

Mitral stenosis is of all the valvular lesions of the heart the most liable to lead to rapidity of the heart's action ; but it seldom happens that the pulse-beat is fast until there has been other evidence of failure of the cardiac compensation. The diagnosis will generally be obvious from the history of acute rheumatism or chorea, the typical facies and malar flush, and the cardiac bruits.

It is difficult to be certain of a diagnosis of irritation of a pneumogastric nerve within the thorax unless the existence of a mediastinal *new growth*, *aneurysm*, or *fibrosis* is already known on account of the abnormal physical signs, the X-ray appearances, the visible tumour, or the varicose distention of the superficial thoracic veins: if an intrathoracic abnormality is known to exist and tachycardia becomes a prominent feature of the case it will probably be due either to mechanical interference with the heart's action or to similar interference with one or other vagus nerve. *Caseous glands* irritating the pneumogastric nerve are still more difficult to be sure of; but occasionally one ventures upon this diagnosis when a child who has been fed on untested or unsterilized cow's milk develops obscure ill health associated with persistent tachycardia. Such diagnosis would be still further suggested if there were at the same time enlarged glands in both sides of the neck, if there were pyrexia without any obvious explanation of it, or if there were any

Fig. 655.—Electrocardiogram in a case of paroxysmal tachycardia in a man. P Auricle wave; R T Ventricular wave. Time marking in $\frac{1}{2}$ seconds. At first sight the tracing looks normal, but when time relationships are considered, it will be seen that there are 16 heart-beats in each 25 one-fifths of a second, so that the heart is making 208 beats per minute. The tracing is from a young man seemingly in perfect health, who had presented himself for examination as a recruit. It was found that when he had been lying perfectly still for a little time his pulse-rate was 72 per minute, but by certain actions, such as holding his breath as long as he could, stooping to touch his toes and remaining in that posture for a minute, he felt a curious sensation in his chest lasting for a few minutes, and simultaneously the pulse-rate rose to over 200 per minute, auricles and ventricles both contracting at this rate and continuing to do so until he lay down and rested for a while. In spite of this he was able to do ordinary work; there was little breathlessness and no trace of any Graves' disease.

evidence of obstruction to the right bronchus, for the right bronchial gland is enlarged far more often than is the left. An X-ray examination may serve to confirm the suspicion (Fig. 155, p. 187).

Diphtheria, *influenza*, and possibly other microbial infections, are occasionally followed by marked and persistent tachycardia during convalescence, or even for weeks, months, or years afterwards. After diphtheria the condition is generally fatal. Influenza is always a dangerous diagnosis because it is so difficult to establish, but in certain cases in which the original diagnosis has been influenza, tachycardia to the extent of 200 heart-beats per minute may be present for months without the patient's suffering from any severe cardiac symptoms, and the condition ultimately terminates in recovery with a return of the heart-beat to the normal rate. Precisely what is the nature of these cases it is impossible to say, but it has been thought by some that the symptom is due to inflammatory changes in the pneumogastric nerve, produced by whatever one means by the toxins of the disease. Whether this be so or not, the fact that persistent tachycardia may arise out of febrile illnesses should be borne in mind.

There are certain drugs which cause the heart's beat to be very rapid, the best known perhaps being *digitalis*, *belladonna*, *thyroid extract*, and *alcohol*. Certain patients suffering from cardiac symptoms seem unable to bear digitalis, the heart being driven into the condition spoken of as *delirium cordis*, though the reverse effect—slowing of the heart, bradycardia—is to be expected in persons who take digitalis well over a long period. When alcohol is the cause of the tachycardia the fact may be obvious, the only difficulty

arising in patients, mainly women, who may be regarded by all as entirely above reproach, but who nevertheless may be addicted to secret drinking. Belladonna in small doses slows the heart, but there are great variations in the degree to which different patients tolerate this remedy, even pharmacoprial doses sometimes producing toxic symptoms of which tachycardia is one. Widely dilated pupils and dryness of the tongue will help to point to the diagnosis in cases in which the belladonna is taken otherwise than medicinally. Tachycardia is the chief symptom by which one recognizes that a patient for whom thyroid extract has been prescribed is receiving too large a dose.

Cordite and allied substances may cause persistent tachycardia ; it is one of the means employed by malingerers to simulate organic heart trouble ; unwilling recruits may chew and swallow cordite to ensure rejection on account of the tachycardia it produces.

Soldier's heart used to be regarded as something mysteriously confined to soldiers, but it is now recognized as being a thing that occurs in every walk of life, though its effects may be more apparent when there is physical stress to bring out the shortcomings of the heart, as in soldiers enduring the stress of campaigns. It is now more generally called D.A.H. (disordered action of the heart), to distinguish it clearly from organic disease of the heart, valvular and otherwise. The symptoms may suggest serious heart disease — precordial pain, breathlessness on exertion, palpitations, fainting attacks, tachycardia, ready fatigue, and a sense of being 'done up' ; but the patients do not die ; the heart is not increased in size, as verified by X-ray measurements ; and electrocardiographic records are normal. The trouble seems to lie in the sympathetic nerves and not in the heart itself ; steady graduated training is the treatment and not the precautions generally adopted in organic heart disease cases. The cause of the trouble is primarily an unstable-ness of the nervous system ; secondly, exhaustion of the nerve forces by excessive fatigue, by terrorizing fear, panic, or nerve shock ; and thirdly, the effect of microbic toxins, such as long-continued slight sepsis from dental infections, nasal infections, trench fever, and so on, or more acute or recent infections such as influenza or a common cold. The diagnosis is made by first excluding all positive evidence of organic heart disease by ordinary physical examination, X-ray examination, and electrocardiographic investigation, and then by clinical gumption, based upon experience of past cases.

Herbert French.

TALIPES. (See CLUB-FOOT, p. 143.)

TASTE, ABNORMALITIES OF. Abnormalities of taste may be grouped under three main headings, namely : (1) *Impairment or loss of ordinary taste sensations* ; (2) *Perverted taste sensations* ; (3) *Sensations of a foul taste in the mouth*. The following conditions may produce these :

1. Impairment or Loss of Taste (*Agustia*) :

a. Due to nerve lesions :—

Paresis or paralysis of the lingual branch of the fifth nerve	Glosso-pharyngeal nerve paralysis Bulbar paralysis
Paralysis of the facial nerve, including the chorda tympani	Cerebral tumour, especially of the uncinate gyrus Hysteria.

b. Due to affections either of the mouth or nose :

A common cold	Other varieties of nasal obstruction
Hay fever (<i>coryza e feno</i>)	Bromism
Atrophic rhinitis	Iodism
Hypertrophic rhinitis	Mercurial and other varieties of stomatitis
Nasal polypus	(p. 661)
Adenoids	Streptococcal superficial glossitis.

c. Febrile conditions, especially when associated with coating of the tongue.

d. After destruction of the nerve endings in the tongue by corrosives taken accidentally or with suicidal intent.

2. Perverted Taste Sensations (*Parageusia*) :

Pregnancy | Hysteria | Epileptic aura | Insanity | Streptococcal glossitis.

3. Foul Taste in the Mouth (*Cacogeusia*) :

a. Local conditions of the mouth or nose :

Caries of the teeth	Septic stumps under tooth-plate
Retention of food particles between healthy teeth	Gumma of the tongue or palate
Furred tongue from any cause	Epithelioma of the tongue or mouth
Excessive smoking	Stomatitis from any cause (p. 661)
Mouth breathing at night	Septic infection of the antrum of Highmore, or an ethmoid, sphenoid, or frontal sinus.
Gumboil	

b. Severe fevers associated with dryness of the mouth and coating of the tongue, especially in :

Pneumonia	Typhoid fever	Peritonitis	Septicæmia, etc.
-----------	---------------	-------------	------------------

c. Septic lung conditions, especially :

Phthisis, with secondary infection of cavities	Gangrene of the lung
Bronchiectasis	Empyema ruptured into the lung
Bronchiolectasis	Liver abscess ruptured into the lung
Fætid bronchitis	Subdiaphragmatic abscess ruptured into the lung.

d. Certain drugs or poisons, especially :

Mercury	Sulphides	Cod-liver oil
Copper	Paraldehyde	Castor oil
Arsenic	Asafetida	Garlic (<i>succus allii</i>)
Lead	Creosote	Salol.
Iodides	Guaiacol	
Bromides	Valerian	

e. Certain foods, such as :

Garlic	Leeks	Shallots.
Onions		

f. Hysteria and functional conditions.

From a diagnostic point of view impairment of taste sensations is of importance only in rare cases. When the impairment is unilateral, it is almost certainly due to a lesion involving either some portion of the third branch of the *fifth nerve*, the *chorda tympani*, or the *glosso-pharyngeal nerve*. It is not often difficult to distinguish between these three. If the *chorda tympani* is involved it is almost certain that the facial nerve will also be affected upon the same side, and this will be evidenced by paresis or paralysis of the face, of the infranuclear type (p. 604) ; there may be excessive watery secretion from the sub-maxillary gland upon the same side ; the commonest condition to cause these symptoms is disease of the middle ear extending to the Fallopiian canal. If it is found that taste is impaired only in the posterior third of the tongue upon one side the lesion probably affects the *glosso-pharyngeal nerve*, and it is very possible that there may be paresis of the same side of the palate or partial paralysis of the pharynx at the same time. When the lingual branch of the fifth is involved the impairment of sensation is in the anterior two-thirds of the tongue on the same side, and furring of the tongue may be localized to the same part. The lesion may be a tumour or an injury affecting the lingual nerve in the mouth ; or it may be part of a more general affection of the fifth nerve of that side with corresponding interference with cutaneous sensibility of more or less of the skin of the face according to the extent to which the different branches of the fifth nerve are involved ; if the motor root is affected the fact can be ascertained by feeling the masseter and temporal muscles, which, when the patient clenches his teeth, do not harden so much on the affected as the sound side.

When sensation on both sides of the tongue is affected it is possible that the lesions described above may be bilateral ; but it is much more likely that the defect is then not primarily nervous, unless it is due to *bulbar paralysis*, the progressive labio-glosso-pharyngo-laryngeal weakness of which is pathognomonic.

When the cause of impaired sensation is in the nose, as in the case of *coryza*, *rhinitis*, *polypi*, or *adenoids*, it will be found that some substances can be tasted easily and others not at all. This depends upon the fact that taste consists of two parts, flavour and savour.

Savour depends upon sensation transmitted by the olfactory nerves. The so-called taste of roast beef for instance; savours will be defective when the nose is the cause of abnormal taste-sensations; while flavours, such as the taste of sugar, gentian, or salt, which are transmitted by the gustatory nerves of the tongue, will still be fully preserved.

The differential diagnosis of the other conditions enumerated in the above list need not be detailed, for the conclusion come to will depend upon the result of careful inquiry into the history, investigation of the abnormal physical signs, and the other symptoms in the case. One would only emphasize the possibility of caries, or decomposing food between teeth that superficially look sound, or septic infection of the accessory sinuses of the nose, being long overlooked, though in each case abnormal taste sensations may be prominent.

Before assuming that abnormal or foul taste is due to *hysteria* it is important to be sure that the patient is not suffering from *chronic streptococcal glossitis* (*Figs. 455-460*, pp. 592, 593), a condition which may give the patient the most intensive suffering, yet with little that is objective to account for it. This condition is analogous to streptococcal pruritus ani; the tongue sufferings may be as intense with the one as is the itching with the other. In some cases there may be almost nothing to be seen wrong with the tongue even on close inspection; but if the case is watched, curious patches of acute reddening will be noticed, developing slowly, spreading slowly, disappearing after days or weeks. When the condition has been present for months there is a tendency for the surface of the tongue to exhibit multiple shallow fissures, often detected only when the surface is stretched laterally by the fingers (*Fig. 457*, p. 592); it is only in exceptional cases that more decided exudative lesions are seen; but the nature of all these cases seems to be the same—they are not hysteria or neuralgia of the tongue, but superficial streptococcal glossitis yielding streptococci in pure growth on culture. Not only is there the perverted taste, but there is also pain in the tongue, varying in severity, sometimes very acute, preventing the patient from eating in comfort, and sometimes prohibiting certain foods altogether, especially vinegar, spices, hot substances, and acid fruits.

Herbert French.

TEETH, GRINDING OF. (See GRINDING OF THE TEETH, p. 335.)

TENDERNESS IN THE CHEST implies that pain is felt when some part of the chest wall is touched or pressed. It is a common symptom; in some instances the pain felt is a direct pain, due to stimulation of sensory nerves actually in the diseased area; in others—perhaps the majority—the pain is a referred pain ('somatic pain'), felt in the skin and subcutaneous tissues that are tender, but due to a visceral lesion remote from the tender area.

CAUSES OF TENDERNESS IN THE CHEST.

These may be classified according to the situation of the lesion to which it is due.

1. *Lesions in the Chest-Wall*: the pain is for the most part direct:

Inflammations of the skin and underlying tissue	Affections of the ribs and sternum	Intercostal neuralgia
Intercostal myositis	Blood diseases	Hysteria
Myalgia	Intercostal neuritis	Herpes zoster
Pleurodynia	Injury of the intercostal nerves	Pleurisy
		Mediastinal disease
		Pericarditis.

2. *Lesions of Thoracic and Abdominal Viscera*: the pain is usually a referred pain, the result of lesions of the:—

Lungs	Diaphragm	Liver.
Heart and aorta	Stomach and œsophagus	

1. Lesions of the Chest-Wall. Tenderness in the chest is probably the chief complaint in *superficial inflammatory lesions* of the chest wall, such as bruises, burns, cuts, mastitis, and superficial infections of all sorts, the diagnosis of which will probably leap to the eye, and need not be discussed further.

Pain will be the chief complaint in *intercostal myositis*, often vaguely called rheumatic, that occurs after chill or strain of the intercostal muscles; but the affected muscles will also be tender on pressure, the tenderness being in the deeper structures, not in the superficial tissues. The condition is also known as *intercostal myalgia* or *pleurodynia*; it has to be distinguished from pleurisy by the absence of friction-sounds on auscultation; and from disease of, or pressure on, the intercostal nerves. No doubt the tenderness is due to irritation of the sensory fibres in the intercostal muscles. Similar, but more transient, pain and tenderness may be met with in the *stitch* to which the untrained athlete is prone.

Tenderness in the chest may result from *disease* or *injury of the ribs or sternum*, when it will be localized to the injured spot; fracture, inflammation, tuberculosis, or new growth may be the immediate cause. If *fracture* is present, a history of injury should be obtainable; the X rays may show the fracture; or crepitus between the fragments on movement, or deformity may be made out. *Sternal* or *costal osteitis*, or *periostitis*, may follow injury; or occur in the course of such diseases as enteric, tuberculosis, pyæmia or septico-pyæmia; the local signs of inflammation (pain, redness, heat, swelling) and the general condition of the patient should make the diagnosis fairly simple. Tenderness in the chest due to *new growth* in the ribs or sternum—such as hydatid, sarcoma, secondary deposits from carcinoma—is generally a late phenomenon, hydatid or malignant disease being known of already in some other part. Tenderness of the ribs and sternum, as well as of the long bones of the limbs, is not rare in certain *blood diseases*, such as pernicious anaemia or leukemia, in which hyperplasia of the red marrow, or excessive accumulation of white cells in it, may occur. The diagnosis depends on examination of the blood. The tenderness is deep, and due to irritation of the sensory nerves of the periosteum or bone; the pain felt on pressure is a direct pain.

Tenderness at certain points of, or all along, the course of an *intercostal nerve* is common in various affections of these structures. The particularly tender spots are three in number, and correspond to the points at which the posterior primary, the lateral cutaneous, and the anterior cutaneous branches are given off, near the spinal column, the mid-axillary line, and the sternal margin, respectively. Such tenderness may be marked in *intercostal neuritis*, which is rare; in *intercostal neuralgia*, which is often diagnosed when some more serious intrathoracic disorder is really present, such as pneumonia or pleurisy; and in cases of pressure on an intercostal nerve, such as may be set up by *abscess* about the spinal column, *aneurysm* of the descending aorta, or *new growth* invading the spinal canal. Whenever a patient complains of severe or obstinate pain and tenderness in the side, careful and repeated physical and X-ray examinations should be made, the possibility that some such deep-seated disease may be present being kept in view before the diagnosis of intercostal neuralgia, or of functional nervous disease (hysteria), is made. In exceptional cases of *hysteria*, zones of tenderness in the chest, possibly, too, Charcot's spasmodic zones, may be found.

Pain and tenderness along an intercostal nerve are common in *herpes zoster*, and may be present before, during, and after the appearance of the characteristic rash. The tenderness often has the three spots of maximum development mentioned above; it is particularly when it occurs in the second half of life that herpes may be followed by a long period of pain and tenderness along the course of the affected nerve. Until the rash has appeared, or in the comparatively infrequent cases when the rash leaves no scarring behind it, the diagnosis of herpes may be difficult; the rash, once seen, can hardly be mistaken.

2. **Lesions of the Underlying Viscera.**—Tenderness in the chest is very frequently a symptom of disease in the underlying viscera, thoracic or abdominal, when the pains to which it gives rise are in most cases referred pains. The tenderness is therefore as a rule superficial, confined to the skin and subjacent areolar and fatty tissues; if these can be drawn aside, pressure can be made on the deeper tissues that normally underlie the tender area without provoking pain. Properly speaking, 'tenderness in the chest' can only refer to tactile hyperæsthesia, or the eliciting of pain on pressure, whether light or heavy. Such tactile hyperæsthesia, or the production of unpleasant sensations or pain by the very lightest touch, is common in neuralgia and in neuroses, or in cases of referred pain. But a similar hyperæsthesia for cold, or less often for heat, sometimes occurs in

the chest in tabetic patients, for example; this may perhaps be regarded as a special form of 'tenderness'. In the same way hyperaesthesia for pain, or hyperalgesia, in which a normally painless stimulus or impression becomes transformed into an acutely painful sensation, is to be regarded as a form of 'tenderness' in the chest. Further, perversions of sensation sometimes occur in organic nervous diseases, such as syringomyelia or tabes. Thus, tenderness may be elicited by the continuous application of a pressure that is painless if applied only for a short time (summation of painful stimuli); or the pain may be first felt some little time after the application of the stimulus to the tender area (retarded sensation).

Tenderness of the chest is a common complaint in *pleurisy*. The physical signs, particularly the friction sounds when the patient takes a really deep breath, should suffice to make the diagnosis simple if a careful physical examination be made. The tenderness is deep as a rule, and not in the skin and loose subcutaneous tissues.

The sternum may be tender as the result of *mediastinal inflammation, tumour, or aneurysm*. The diagnosis in these cases must be made on the results of the physical and X-ray examination.

Tenderness with pain over the precordia is fairly common in *pericarditis*, diagnosed by the canter rhythm and the pericarditic rub. It may be so extreme as to preclude percussion or a satisfactory physical examination. Similar pain and tenderness have also been found at the epigastrium and the upper costal angles in these cases—due, perhaps, to involvement of the diaphragm in the inflammatory process.

Chest tenderness is not rare in cases of *acute or chronic disease of the lungs*, particularly *tuberculosis*; in these, it is hard to be sure that one is not dealing with referred pains due to old or recent pleurisy or pleural adhesions. The tenderness may be either superficial or deep; sometimes it is so marked as to be elicited even by the pressure of the clothes. It is generally felt most about the region of the apices of the lungs, the curve of the shoulder, or the scapula. It is often a very chronic trouble, vanishing during periods of general improvement, returning again when the patient's health is low or the pulmonary lesion is progressing. Similar tenderness is often met with in *acute bronchitis*, or with *chronic bronchitis and emphysema*; the diagnosis must be made on general lines. It must be remembered that identical areas of referred chest-tenderness may be observed in disorders of such various organs as the heart, lungs, liver, and stomach; and that a patient may be long treated for 'rheumatism' of the shoulder, for example, when he is really suffering from such widely different disorders as tuberculosis, gall-stones, gastritis, carcinoma mammae, or coronary artery sclerosis. Tenderness along the lower chest wall, corresponding to the attachment of the diaphragm, is a relatively common symptom in any case in which there is recurrent or excessive cough; it is the result of the straining the diaphragm suffers in the coughing paroxysms, and is particularly frequent perhaps in cases of *chronic bronchitis, mediastinal new growth, and pulmonary tuberculosis*; the distribution of the tenderness and the history serve to indicate the nature of its cause.

Direct tenderness about the precordia is sometimes prominent in *heart disease*; as a rule, however, the tenderness is due to hyperaesthesia of referred origin. It is most marked in *angina pectoris*, and often persists after the anginal pains have passed off. Both the pain and the tenderness are felt within the area of distribution of the first to the eighth dorsal nerve-roots; the roots usually receiving the first and most intense impressions are the second dorsal. The left ventricle, the commonest primary seat of pain, is in relation with the second to the fifth dorsal nerve-roots; the auricle with the fifth to the eighth; the ascending aorta with the third and fourth cervical and the first to the third dorsal. These nerve-connections explain the extensive radiation and wide distribution of the tenderness and pain in the superficial tissues that may form such prominent symptoms of heart disease, especially when there is coronary artery sclerosis from atheroma, or syphilitic disease of myocardium, aortic valves, and aortic arch; for the chest, neck, and arm may all be affected. The tenderness of angina pectoris commonly occupies the same areas as the pain, takes the form of a soreness, smarting, or of hyperalgesia to touch, and may last for days after the pain is over. In some cases, touching or stimulating the hyperalgesic area on the chest, arm, or neck, may reflexly induce an anginal attack—even the pressure of a stethoscope applied for auscultation may suffice—which is a strong argument for regarding the tenderness as a viscerosensory reflex or a referred tenderness. Such anginal

attacks and tenderness are commonest in coronary sclerosis, aortic aneurysm, aortic reflux, and acute aortitis; they may also be seen in any form of heart disease in which hypertrophy and dilatation have taken place, and the heart has to do more work than it can manage, for example with raised blood-pressure and arteriosclerosis, or with adherent pericardium. In well-marked cases the cardiac origin of areas of tenderness in the chest should not be difficult to diagnose owing to their association with severe anginal pains on the one hand, and with the fact that the pain is brought on by exertions or emotions that increase the work of the heart. Identical areas of tenderness may be found in pleurisy or chronic pulmonary tuberculosis; but here the pain will be connected with respiration or coughing in an unmistakable manner, and there will be the history and signs of pulmonary rather than of cardiac disease. Identical areas of chest tenderness may be found in diseases of the stomach, in the areas of distribution of at any rate the fourth and fifth dorsal nerves; the diagnosis here will turn on the history of gastro-intestinal disorder, and on the radiation of the pain and the discovery of tenderness in the epigastrium.

Tenderness in the chest may result from *injuries* or *inflammations of the diaphragm*, the lower costo-chondral margin being affected. The diaphragm is innervated by the phrenic nerves mainly, and so is connected with the third, fourth, and fifth cervical nerve-roots; accordingly, referred diaphragmatic pain and tenderness may also be felt in the top of the shoulder, an area innervated by the fourth cervical nerve. In most instances, the tenderness of these areas will be due to *diaphragmatic pleurisy*.

Diseases of the stomach, particularly *gastric ulcer* and *flatulent dyspepsia*, may give rise to pain and tenderness in the chest that may be very hard to distinguish from those due to cardiac disease. As a rule, the history of gastric disturbances should be of great assistance in coming to a correct diagnosis; though flatulence and temporary gastric upsets are not infrequent in true angina pectoris. Further, the pain and tenderness due to diseases of the stomach are mainly abdominal, are in the epigastric and left hypochondriac regions, and in the lower half of the back of the chest; whereas in cardiac disorders they are characteristically situated higher up in the chest and back, tending to radiate down one or other arm, the left in particular. Electrocardiograms may be required to show whether the heart action is normal or not.

It is possible that disease or painful stimulation (as by hot drinks) of the *œsophagus* may produce an area of referred tenderness in the chest, over the lower third of the sternum and in the middle line, in correspondence with the pain that is felt here in these conditions.

Tenderness in the right side of the chest near the costal margin is not rare in *diseases of the liver* and *gall-bladder*, corresponding to the cutaneous distribution of the seventh, eighth, and ninth dorsal nerves; for the most part, however, the pain and tenderness are in the epigastrium and the right hypochondrium. The right phrenic nerve (third to fifth cervical) sends twigs to the liver and gall-bladder, so that tenderness and pain may also be felt in the right shoulder, just as they may be in disorders of the diaphragm. It is particularly in cases of gall-stone or biliary colic that these areas of tenderness are likely to be found. In patients with hepatic abscess the spread of inflammation to the chest wall may give rise to direct pain and tenderness in the chest, with the development of characteristic local and general symptoms and signs; the diagnosis here will have to be made from such things as axillary abscess, empyema making its way through the chest wall, or abscess arising in the chest wall.

TENDERNESS IN THE EPIGASTRIUM.—(See PAIN IN THE EPIGASTRIUM, p. 536.)

TENDERNESS IN THE HYPOCHONDRIUM. (See PAIN IN THE HYPOCHONDRIUM, p. 553.)

TENDERNESS IN THE ILIAC FOSSA. (See PAIN IN THE ILIAC FOSSA, p. 555.)

TENDERNESS IN THE JOINTS.—(See JOINTS, AFFECTIONS OF THE, p. 423.)

TENDERNESS IN THE LIMBS. (See PAIN IN THE LIMBS, p. 568; and SENSATION, SOME ABNORMALITIES OF, p. 747.)

TENDERNESS OF THE SCALP occurs in two main varieties :—**1. Direct Tenderness**, due to injury or disease, such as :—

Bruising or infected wounds	Lupus erythematosus
Inflammation or suppuration complicating pediculosis, ringworm, favus, eczema, pruritus, acne, etc.	von Recklinghausen's disease
Herpes, dermatitis herpetiformis, erysipelas	Sclerodermia, Brocq's 'pseudopelade'
	Diseases of the skull rickets, syphilis, tumour.

2. Referred Tenderness, either due to disease elsewhere, or functional :—

Meningitis, increased intracranial pressure, intracranial tumour or abscess, concussion of the brain, otitis media	Neuralgia, major and minor, whether primary or due to disease of the eyes, ears, teeth, or viscera
	Neurasthenia and hysteria.

Fig. 656 exhibits the cutaneous nerve-supply of the scalp and face, indicating the areas in which tenderness and pain are to be expected when disease or disorder of the various nerves is present.

If tenderness in the scalp is due to *bruising or wounds*, it should not be difficult of diagnosis when the history has been obtained. A similar tenderness is naturally to be expected when inflammation or suppuration occurs as a complication or later stage of any of the numerous skin diseases to which the scalp is liable, such as *pediculosis*, *ringworm*—a suppurating ringworm is known as *kerion*, *seborrhoeic dermatitis*, *favus*; the itching of *eczema* or *pruritus* may be so severe as to lead to scratching which breaks the skin, with the result that *impetigo* ensues. In young men and women *acne* may spread back to the scalp from the forehead, face, or neck; *acne decalvans* is a mild staphylococcal infection of the hair-follicles that creeps slowly across the scalp, and leaves it bald by destroying the hair-follicles. *Furunculosis* of the scalp, and inflammation of a *sebaceous cyst*, need only be mentioned in this connection.

In *herpes ophthalmicus*, or herpes zoster of the area supplied by the ophthalmic or first branch of the trigeminal or fifth cranial nerve, extreme tenderness over the affected area may be noted while the eruption lasts; and after it has disappeared, especially in patients over fifty years of age, tenderness and itching may be left behind for many months or years, sometimes with abnormal pigmentation.

Dermatitis herpetiformis (p. 918) is a somewhat similar grouped vesicular or bullous eruption, with ringed and other erythematous lesions, but characterized by a much more extensive distribution than herpes zoster; when it involves the scalp much tenderness may ensue, although the chief complaint will be of itching, and the course of the disorder is long and uncertain. *Erysipelas* of the face and scalp is usually diagnosable at sight. *Lupus erythematosus* of the scalp may cause tenderness while progressing actively, when it may resemble even a severe persistent erysipelas; as a rule it is a very chronic, slowly progressive disorder, commoner in females than in males, starting between the ages of twenty-five and forty-five, producing smooth depressed areas of complete permanent baldness, reddened by abundant injected venules. In *von Recklinghausen's disease* subcutaneous neurofibromas are found all over the body in association with freckling and pigmentation; occurring on the scalp, these tumours will make it tender, whereas the tumours of *molluscum fibrosum* (Fig. 657), a disorder at first sight resembling von Recklinghausen's disease, are not sensitive to pressure. *Sclerodermia* of the scalp may occasion much tenderness, particularly in its early stages; it is a chronic diffuse infiltration of the skin that ends in atrophy, and by many is supposed to include the 'pseudopelade' of Brocq, an atrophic indurative affection of the scalp giving rise to depressed areas of

Fig. 656. The cutaneous nerve-supply of the scalp. G.A., Great auricular nerve; G.O., S.O., and Th.O., Great, small, and third occipital nerves; V₁, V₂, V₃, Ophthalmic, superior maxillary, and inferior maxillary divisions of the trigeminal (or fifth cranial) nerve.

absolute and permanent baldness that adhere to the underlying skull, and connected by Brocq with alopecia areata.

Tenderness of the scalp is common in *rickets*, and is the main cause of the head-rolling and restlessness of the recumbent rickety child. It can often be diagnosed at sight by the thinness of the hair or positive baldness of the occipital region to which the head-rolling leads. A similar tenderness of the cranial bones is seen in *congenital syphilis*, and is caused by the rarefying (craniotabes) or hyperplastic (hot-cross-bun skull) osteitis present. In adults the skull may be tender from *secondary syphilitic periostitis* or *tertiary gumma*; besides the tenderness, pain is present, and is characteristically worse at night. *Tumour*

of the cranial bones may give rise to tenderness of the overlying scalp or periosteum; in adults such tumours are usually secondary to malignant disease of the breast, thyroid gland, testis, or prostate. In children they are often secondary to sarcoma of the suprarenal gland, and may be the first clinical evidence that anything is amiss.

Tenderness in the scalp may be due to organic disease that is not in direct connection with it. In *meningitis*, whether syphilitic, tuberculous, or due to pus-producing microbes, local or general tenderness of the scalp may be a marked feature; and the same is true in cases with *increased intracranial pressure* due to any cause whatever. The chief complaint, however, will be of HEADACHE (p. 369). With *intracranial tumour* the scalp and periosteum are sometimes tender to pressure in the neighbourhood of the growth; the associated signs, such as vomiting on change of position, slow pulse, optic neuritis, and local paresis or paralysis, should aid the diagnosis. Tenderness of the scalp in the occipital region and below it has often been noted after *concussion of the brain*, whether mild in degree or severe, and apart from neurasthenia; the pain and tenderness may each be both superficial and deep.

Fig. 657.—Molluscum fibrosum of many years' duration.
(By Capt. S. C. Bagn, I.M.S.)

Tenderness of the scalp is often marked in *neuralgia*, a vague term applied to any severe pain that follows, or seems to follow, the distribution of a nerve. In *trigeminal neuralgia*, *neuralgia major*, or *tic douloureux*, the pain and tenderness often spread back to the vertex and parietal eminence, in correspondence with the cutaneous distribution of the first or ophthalmic branch of the fifth nerve. Pressure over the tender area will often bring on a paroxysm of pain; yet while the pain is raging, the patient often gains some relief by firm pressure over the painful part. When the paroxysm is recently past pressure does not have any obvious effect in some cases. Identical neuralgic pain and tenderness may be met with in the rare cases where a tumour presses on the trigeminal nerve or its roots, as may happen in patients with meningeal new growths. Definite loss of sensation occurs if the nerve is involved in a tumour, whereas in *tic douloureux* there is no anaesthesia; in addition, the other signs of intracranial tumour should be looked for.

In another group come the cases of *neuralgia minor*, in which pain and tenderness in the scalp form a visceral reflex, and are due to disease in the eyes, teeth, ear, or thoracic or abdominal viscera. A referred visceral pain usually brings with it superficial tenderness, and both the pain and the tenderness are found over 'segmental' areas, or areas that do not correspond with the distribution of the peripheral nerves, but follow a central distribution (Figs. 658, 659). In other patients, however, the same lesions produce areas of pain, and less often of tenderness also, that do follow distributions corresponding with those of the peripheral nerves; and these are described as cases of *neuralgia minor* proper.

To give examples of reflex neuralgia, disease of the *upper bicuspid*s may cause pain and tenderness in the temporal region; disorders of the *eye*, particularly astigmatism and hypermetropia, iritis, and glaucoma, may cause headache and tenderness spreading from the forehead to the vertex and to the temporal area; suppuration in the *middle ear* may make the whole side of the head tender. Certain areas on the head are segmentally united with other areas on the body; the temporal area of the scalp is connected thus with the seventh dorsal segment, and so diseases of the *heart, lungs, or stomach* may all bring about temporal pain and tenderness, associated with the segmental area of cutaneous tenderness about the level of the epigastrium that directly represents the seventh pair of dorsal nerves. It is probable that a number of patients with undetected disease of the teeth, eyes, ears, or viscera, are treated for 'neuralgia' for long periods, when a more careful examination of their history and investigation of their physical condition would lead at once to the proper diagnosis.

In a certain number of cases pain and tenderness in the scalp are due to *general diseases* such as diabetes mellitus, malaria, and rheumatism—a fact that leaves room for much latitude in diagnosis.

In both *neurasthenia* and *hysteria* complaints of pains and tenderness are common, and the scalp may be affected just as any other part of the body may. The neurasthenic often has occipital tenderness, with pain referred to the hair; brief mental effort may bring on pain and tenderness in the sinuiput or vertex. The hysterical patient may be prostrated by headache, with extreme tenderness of the scalp; but care to exclude organic disease of every sort should be taken before the diagnosis of neurasthenia or hysteria is made in a patient complaining of tenderness in the scalp. Any conditions tending to build up the strength and improve the nutrition of neuralgic, neurasthenic, or hysterical patients are likely to lessen the pains and areas of tenderness of which they so often complain; conversely, these persons are always much worse when their health is low, and particularly when they are anæmic.

Figs. 658, 659.—THE SEGMENTAL AREAS OF THE SCALP (after Head).

TENDERNESS IN THE SPINE occurs in two different sets of conditions. In the first it is due to local disease of the skin or subcutaneous tissues, fasciæ, muscles, bones, or nerve-tissue in the immediate neighbourhood of the spine; and the pain felt when the tender spot is touched is a direct pain. In the second there is no local disease, and the pain felt on stimulation of the tender area is a referred pain, due in most cases to organic disease of one or other of the viscera, in a few to some obscure nervous disorder. The tenderness varies widely in degree. In the severest cases, whether direct or referred, the pain may be such that the patient cannot endure even the light pressure of the clothes ordinarily worn, and is in agony the moment a finger is laid upon the tender place.

When due to Local Disease, the tenderness is usually associated with rigidity of the spine in the tender section, a protective reflex designed to give rest to the diseased part. This is particularly well marked when it is bone—the vertebral column—that is diseased. A similar but less complete and more extensive rigidity will be noted when the local disorder is in the muscles or fasciæ of the back. Should the local disease or injury be so extensive as to involve or compress the spinal cord, special symptoms (girdle-pain, paresis, anaesthesia, etc.) will be added. The chief morbid states in which such tenderness of the spine occurs are summarized in the following table:—

<i>Diseases of the skin and subcutaneous tissue</i>	{ Injury, infected wounds, abscess-formation, actinomycosis, etc.
<i>Diseases of the muscles, fasciæ, or nerves</i>	Gout, rheumatism, injury, herpes, etc.
<i>Diseases affecting the vertebrae</i>	{ Tuberculosis and other infections Caries sicca, spondylitis deformans, and 'typhoid spine' Erosion by aortic aneurysm Invasion by malignant disease Injury
<i>Traumatic neurasthenia, with local lesions that are not demonstrable</i>	{ 'Railway spine.'

To consider these lesions in detail : Obviously the skin and subcutaneous tissues may be tender over the spine after falls or blows on the back, infected wounds, in acne and furunculosis, in abscess-formation, whether the infection is derived from without, or from within as in pyæmia : a *psoas abscess* may point and discharge on the back over the vertebral column. Tenderness in the spine due to *affections of the fasciæ and muscles* may be experienced by any ill-trained person who over-uses or strains his spinal muscles : it is also common in *gouty* patients : and frequently it is associated in the rheumatic with attacks of *lumbago*. Deep-seated inflammations in this region are not rare, and are seen usually in connection with *spinal caries* : less often the inflammation may be due to *pyæmia*, *empyema* perforating spontaneously, *trichiniasis* and other very rare forms of *myositis*, when they chance to attack the spinal region. In a few instances, no doubt, *disease of the spinal nerves*, particularly when their posterior primary divisions are affected, gives rise to tenderness in the spine as well as along the course of the nerves themselves : this may occur when pressure on the nerves or their roots exists, and in cases of *herpes zoster* or *neuritis*. Most of the causes of spinal tenderness enumerated above should not be difficult of diagnosis if a careful examination of the patient be made, and his other signs and symptoms of disease be noted.

The cases in which the tenderness is due to disease of the vertebrae are more serious from the point of view both of prognosis and treatment. Excluding spinal trauma, which usually declares itself obviously and is considered below, the three main disorders which affect the vertebrae in this connection are *tuberculosis*, invasion by *malignant disease*, and erosion by an *aneurysm*. In other rarer instances they may be affected with similar symptoms and results by *actinomycosis*, *pyæmic abscess*, the spread of infection from adjoining parts (retropharyngeal, mediastinal, subdiaphragmatic, perinephric, or pelvic abscesses), *hydatid disease*, *spondylitis deformans*, and *vertebral arthritis* due to typhoid bacilli, the gonococcus, and other microbes. When caused by *vertebral tuberculosis*, the spinal tenderness is local, and is generally accompanied by more or less angular deformity of the spinal column, collapse of the diseased and softened anterior part of the vertebral body causing abnormal projection of its dorsal spine at the same time. If it is the posterior part of the affected vertebra that collapses, the spinous process will sink inwards : it must be remembered, however, that congenital defect or deficiency of a spinous process is not very rare, and may be mistaken for the result of injury or disease. Whether deformity accompanies spinal caries or no, rigidity of the diseased part of the spinal column is sure to be present. It is maintained by involuntary contraction of the appropriate muscles, and becomes conspicuous when the patient is encouraged to bend his back in any direction, or to rotate the body on the pelvis. In addition, pain will be felt in the back when the patient's vertex, shoulders, sacrum, or legs are jarred : his gait, too, and method of holding himself and turning designed to relieve the diseased part of the spinal column from shock or strain, will be characteristic. In children who are not well looked after this spinal tenderness and deformity may be unnoticed and the diagnosis of spinal caries not established until a psoas abscess has formed and has declared itself by pain in the leg, or lameness. The importance here of early diagnosis cannot be overstated : spinal tuberculosis is commonest in children, but may occur at any age. It often happens that rickety children are suspected of 'spinal disease' by their parents : they present marked spinal curvature, due to flabbiness of the muscles, and, like all their bones, their spines

may be tender on pressure. But there is no localized spinal tenderness in rickets, there is no angular deformity, the spinal curvature vanishes when the child is suspended by the head or arms, no pain is caused by jarring or rotating the spinal column, and there is no rigidity of the back: the other ordinary evidences of rickets will be present. In adults, however, and particularly during the second half of life, it may often be difficult to determine whether a persistent tenderness over some part of the spine, associated with pain and rigidity, is due to *tuberculosis*, *aneurysm*, or *malignant disease* affecting the vertebral column, or merely to *myositis* or *infective fibrositis* of the soft parts over the spine. The occurrence of angular curvature, due to softening and collapse of the vertebral body, would argue in favour of tuberculosis, being comparatively rare in aneurysm or malignant disease: evidence of tuberculous mischief in the patient's joints, lungs, or larynx, a history of cough or blood-spitting, or a marked family history of tuberculosis, would all point in the same direction. Aortic aneurysm, eroding the vertebral column and causing pain and tenderness by pressing on the nerves in its vicinity, would be suggested if the patient were a middle-aged man giving a history of syphilis. Examination under the X rays and testing for Wassermann's reaction might be of great assistance here: deep abdominal palpation, under an anæsthetic if necessary, might reveal the expansile pulsation of an aortic aneurysm. Secondary deposits of malignant disease, invading or encompassing a vertebra, may occasion marked spinal tenderness and pain in the back of the severest description: in rare cases the malignant growth may be primary. The vertebrae are the bones most often invaded by secondary malignant growths: the primary growths most frequently responsible for secondary deposits in the bones are carcinoma of the thyroid, testis, prostate, and mamma, primary sarcoma of bone, and melanotic sarcoma. Here again the diagnosis may be very difficult, in the earlier stages of the disorder particularly, because the primary growth may be small and deep-seated, and may have given rise to no signs or symptoms leading to its discovery, so that the presence of secondary deposits is not suspected. In the later stages the growth often burgeons into the spinal canal and causes symptoms of paraplegia by compressing the spinal cord. When this occurs the diagnosis is easier, for the site of the compression may be indicated by a girdle-pain and a zone of hyperæsthesia: while anæsthesia, with paresis or paraplegia, is found below it, the sphincters are affected, the knee-jerks are increased, and ankle-clonus and Babinski's extensor plantar reflex can be elicited. But it may be impossible to find any definite physical signs in a patient complaining of very severe and intractable pain and tenderness in some part of his spinal column: and most physicians must have met with sad cases where such patients have been treated as hysterical or as malingerers, the honesty of their complaints failing to win recognition until a carcinomatous or other pathological basis for them has been established at an autopsy.

Little more need be said about most of the other local diseases that may make the affected region of the spine both tender and painful. *Caries sicca* is the name given to an obscure rarefying osteitis of chronic course, non-suppurative, that may attack the vertebrae. The signs and symptoms of *vertebral actinomycosis* resemble those of tuberculosis. In *chronic pyæmia* a vertebral abscess may arise, and in patients with abscesses in the spinal region such as *pelvic*, *perinephric*, *subdiaphragmatic*, *mediastinal*, or *retropharyngeal* a spread of infection to the vertebrae may conceivably occur, giving rise to tenderness in the affected part of the spine: *hydatid disease* of the spinal canal or vertebral column may do the same in persons exposed to echinococcus infection. But in all these instances the tenderness in the spine will be but a minor symptom of a serious and more or less acute disorder, with other features that are more characteristic. Tenderness in the spine is often marked in *spondylitis deformans* (Figs. 621, 622, p. 796), the name given to practically any chronic non-suppurative form of vertebral arthritis. It is no doubt an infective process, and occurs after gonorrhœa, influenza, enteric fever (the 'typhoid spine'), tonsillitis, and other bacterial disorders, or may be due to microbic-toxic absorption from septic teeth. It is characterized by stiffness in some portion of the vertebral column, with irregular deposits of new bone in the adjoining ligaments, particularly the anterior common ligament, seen by the use of X rays. The chief sign is stiffness in the back, and in a few of the cases osteo-arthritis of some joints of the limbs occurs as well: in instances where the hip or shoulder is thus involved the disease has been named '*spondylose rhizomèlique*' by Marie. Men are affected four or five times as often as women, and the disease usually begins

between the ages of twenty and fifty. Its diagnosis may be difficult, because the chief complaint may be of pain in the hips, legs, abdomen, or thorax, or of 'sciatica' or 'lumbago', so that disease of the vertebral column may be neither suspected nor looked for. In most patients, the affected region of the spine is tender; much spasm of the dorsal muscles is found in the more acute cases, while in those of long standing, atrophy from disuse will be found. The *typhoid spine* is a rare sequela of enteric fever, usually occurring early in convalescence. The patient complains of tenderness and the most acute pain in the lower part of the vertebral column, after an initial stage of backache. Fever is present at first in half the cases, and no doubt the condition is commonly due to vertebral periostitis set up by the *Bacillus typhosus*. The symptoms last for many months as a rule, and deformity of the spine is left in half the patients; but suppuration of the affected vertebrae seems to be unknown. Men are affected more often than women. In milder cases no physical signs of vertebral disease appear, and so the affection has been described as hysterical, the spine as an irritable spine; in yet other instances, the spinal cord appears to be involved, as if the periostitis affected the spinal canal, loss of control over the sphincters being observed, with paresis of the legs, and changes—usually increase—in the reflexes.

Tenderness in the spine due to *injury* may be the expression of either organic or functional disease resulting therefrom, and the precise diagnosis may be extremely difficult. The trauma is usually a railway, motor-car, or other accident of locomotion ('railway spine'), a fall, a sudden shock or concussion; in another group of cases it is either a single sudden muscular overstrain, due to over-exertion or the effort to avoid an accident, or the more chronic overstrain to which rowing men, football players, and the like are exposed. A gross injury may produce fracture of a vertebra, with or without displacement of the fragments such as can be demonstrated by the use of X rays, subperiosteal or subdural hæmorrhage, hæmorrhage into the spinal canal, hæmorrhage into or bruising of the cord, all of which will give rise to localizing cord-symptoms (girdle-pain at the level of the lesion, varying degrees of paresis and anaesthesia below it) when the lesion is marked. At the other end of the scale are found the sufferers from *traumatic neurasthenia*, who have been exposed to identical injury or overstrain, but present no definite signs of disease in the spine or cord, although quite incapacitated for months or years by weakness and severe pains in the injured region. These patients often have increased knee-jerks; but definite evidences of organic disease are wanting, the sphincters are unaffected, Babinski's extensor plantar reflex is not obtained, muscular wasting is not found unless from disuse, and the various pains and tendernesses of which complaint is made have a neurasthenic or even a hysterical distribution and character. Traumatic neurasthenia may follow surgical operations or comparatively slight injuries to the head, back, or testicle, in addition to the severer traumas and strains already mentioned; and it must be noted that a delay of one or more weeks, an incubation period, may intervene between the receipt of the injury and the development of the neurasthenic pains. It would be unfair to take such a delay as evidence of a hysterical factor in the case, or of malingering.

It is clear from the foregoing paragraph that traumatic neurasthenia includes cases in which it is not possible to say for certain whether a local organic lesion of the spine exists or not. Such instances form a natural transition to those in which there is:—

Tenderness in the Spine due to Functional Disorders or to Disease in Other Parts of the Body. In very few of these is there any deformity of the spinal column; it is flexile and not rigid; and pain is rarely produced when it is carefully bent, twisted, or jarred, so long as direct stimulation of the tender part is avoided. As a rule the tenderness is superficial rather than deep, and it is often associated with other areas of tenderness in the side or front of the body. In *hysteria*, complaint of pain and tenderness in the spine and back is not rare—the 'hysterical spine'. The tenderness over the vertebrae is often accompanied by tenderness on either side of them; in extent it may change from time to time, involving a single vertebra or even most of the vertebral column. In *neurasthenia* the spine may be tender from top to bottom, and more or less rigidity is often found also. When the tenderness is localized to a small part of the back, it may easily be taken as evidence of local organic disease; but the presence of other neurasthenic symptoms—headache, irritability, fatigability after brief exertion—and the absence of signs of definite local disease or involvement of the cord, should help in the diagnosis. To distinguish clearly between neurasthenia and hysteria is often difficult, and particularly so in the milder cases

of traumatic neurasthenia, because they may develop hysterical features such as areas of anesthesia, a craving for sympathy, a tendency to exaggerate the symptoms, and so forth. The harmful effects of mental worry on neurasthenia, of the uncertainty attaching to an impending law-suit in which, perhaps, damages for injury are being claimed, are well known.

Tenderness in the spine is very commonly a reflex from disease in one or other of the thoracic, abdominal, or pelvic viscera. The tenderness is characteristically superficial in these cases, and acute pain may result from light pressure on the area involved; and if the tender tissues can be pulled aside sufficiently, it will be found that pressure on the spine itself causes no pain whatever. The different viscera produce this tenderness with some regularity in different and definite spinal areas, a scheme of which is given in *Fig. 660*.

The organs and diseases most often giving rise to this referred tenderness and pain in the spine are as follows: The *aorta*, in aortitis, arteriosclerosis, and aneurysm; the *heart*, in coronary sclerosis particularly, myocarditis, myocardial fibrosis, acute dilatation, and failing compensation; the *stomach*, in gastric ulcer, malignant disease, gastritis; the *liver*, in cholelithiasis, cholangitis, new growth, and the venous congestion of tricuspid reflux; the *intestine and rectum*, in acute inflammatory disorders, constipation, and carcinoma; the *uterus*, in labour, menstruation, inflammatory affections, and new growth. It would appear that the lungs, whether inflamed or wounded, do not give rise to a referred tenderness; on the other hand, the whole or any part of the thoracic spine may become tender in disorders of the *pleura* such as pleurisy, pleural adhesions, or new growth. To illustrate the frequency with which pain and tenderness of the spine occur, the axiom of many hospital out-patient departments may be quoted, that there is no woman in London who has not got a pain at the bottom of her back—a libel on the sex, one may hope.

The referred pains and tendernesses disappear or are relieved with the cure or relief of the cardiac, gastric, hepatic, uterine, or other disorder to which they are due. The diagnosis of the cause of tenderness over the fourth dorsal vertebra, for example, which may be due to disease of the heart, pleura, or stomach, must be made on general lines, and by consideration of the other signs and symptoms exhibited by the patient.

E. Farquhar Buzzard.

Fig. 660. Areas of referred spinal pain and tenderness *after Mackenzie*. *A*, In diseases of the heart; *B*, In diseases of the stomach; *C*, In diseases of the liver; *D*, In diseases of the rectum and uterus.

TENESMUS signifies frequent and painful inclination to go to stool, associated generally with straining and griping but with very little evacuant result. A precisely similar condition affecting the bladder is spoken of sometimes as *vesical tenesmus*, but a better known term for this is **STRANGURY** (p. 797).

The severest examples of rectal tenesmus are afforded by *acute dysentery*, in which, after the acute onset of the disease, copious loose fecal motions are passed to start with, then smaller and smaller quantities at a time, and after this, when there is practically nothing left to come away from the bowel, the desire to defecate urgently and repeatedly may still recur perhaps every ten minutes with painful straining, causing the patient to groan or cry out, but with practically no evacuant result beyond a little fluid with mucus and blood. The diagnosis in these cases is generally based upon the fact that the patient is or has been resident in some part of the tropics where dysentery is endemic; the nature of the dysentery itself, whether due to the ameba of dysentery, or to Shiga's dysentery

bacillus, or to other less well known bacilli, is made upon the results of bacteriological investigations of the stools.

Similar tenesmus may also occur in acute *cholera* when the stage of rice-water stools has been reached : here again the diagnosis depends upon the fact of residence in a part where cholera is endemic, or where cholera has recently broken out in epidemic form : it is confirmed by the discovery of the comma bacilli of cholera in the stools.

In this country there are various types of *acute infective diarrhœa* which may simulate cholera to such an extent that, although not cholera at all, they have been grouped together under the heading of *cholera nostras*, and in such cases tenesmus may be extreme. Temporary acute diarrhœa with much tenesmus may arise in school-boys and others from the eating of unripe apples or other fruit : after a brief but acute illness and perhaps a drastic purge, rapid recovery is the rule. More serious are the acute attacks of vomiting and diarrhœa which are familiar under the name of *ptomaine poisoning*, the cause being bacilli allied to Gaertner's bacillus ingested along with some article of diet. Cases of ptomaine poisoning may be sporadic, but occasionally as the result of many persons eating the same cold pork pie perhaps, or something of that kind at a public function, acute epidemics are recorded, some of the cases ending fatally. The bacteriology of the condition is complex : different micro-organisms, including not only Gaertner's bacillus, but also Morgan's bacillus A, Morgan's bacillus B, and probably others, are at the root of different outbreaks. The diarrhœa is at first painless though frequent, but severe tenesmus ensues after the bowel has become empty of practically everything but a little fluid together with mucus and exuded blood.

Chronic dysentery is less often associated with tenesmus than is the acute form, but a considerable degree of tenesmus may none the less be complained of by those who have suffered from dysentery in the tropics and, having returned home not yet cured, still suffer from repeated diarrhœa to the extent of perhaps twelve or fifteen motions a day. The same applies to cases of *colitis*, whether muco-membranous or ulcerative, arising at home. It may be very difficult in some cases to exclude malignant disease of the bowel unless the history is too long for this. In cases of doubt much may be learned by passing the sigmoidoscope and actually seeing the inflamed or ulcerated mucous membrane of the lower part of the bowel.

Intussusception will only cause tenesmus when the lower end of the intussusceptum has reached the pelvic colon or the anus. The symptoms will be those of intestinal obstruction, and when the intussusception is felt per rectum or seen protruding per anum the only difficulty will be to distinguish it from a rectal polypus or prolapse of the rectum. The condition is very much commoner in infants about nine months old than in any other class of patient, and at this tender age tenesmus will not as a rule be obvious. In older patients a subacute or chronic intussusception is fortunately rare, and it is seldom diagnosed accurately previous to operation.

Acute summer diarrhœa and vomiting of infants is allied to ptomaine poisoning and is similarly due to one or more of the enteritic micro-organisms : tenesmus may be very severe in infants as well as in adults.

Another malady allied to ptomaine poisoning, to tropical dysentery, and to acute summer diarrhœa and vomiting of infants, is so-called *asylum dysentery*, of which the symptoms and results are similar to those of tropical dysentery : asylum dysentery also has a bacterial cause, and the micro-organism producing it has been the subject of considerable investigation. The difficulty of deciding the precise nature of the infecting organism in all these cases depends upon the similarity between the different possible bacilli and the ordinary bacillus coli which always abounds in the evacuations.

Acute tenesmus may be a marked feature in some cases of *poisoning by arsenic* : the diagnosis of this cause may be obvious either on account of the patient having taken an over-dose with intent to commit suicide, when choleraic diarrhœa and much tenesmus may come on subsequent to the initial vomiting and collapse : or because, in less acute cases, the patient is known to be taking large doses of arsenic in his medicine for instance, in the treatment of chorea or of pernicious anæmia : indeed, the occurrence of diarrhœa with griping rectal pains and tenesmus is one of the difficulties that presents itself in continuing the arsenical treatment of pernicious anæmia and other blood diseases to the extent that one would like. On the other hand, even when arsenic is the cause of diarrhœa and

tenesmus it may sometimes be difficult to make certain of the fact although some suspicion of it may have arisen in the mind of the physician. Accidental contamination of the water or of some food may have occurred; or, still more important, some member of the household may be administering arsenic surreptitiously, perhaps as weed-killer, either with a view to getting rid of the individual concerned, or occasionally even without any particular object—for instance, in the case of some hysterical servant girls who have been known to administer poisons in a household in this way apparently without any material object at all. The circumstances of the case may make one suspicious and lead to a careful watch being kept, or perhaps an analysis of the water-supply or of some suspected food will lead to the detection of the arsenic. In case of doubt one might have to resort to the expedient of taking the patient entirely away from the house in which she has been living, and from amongst the individuals with whom she has been associated, in order to see whether the symptom persists when she is secluded in a nursing home or elsewhere, or whether it disappears there to return again when she goes home. Analysis of the hair for arsenic in cases of this kind will seldom be available as a test of the diagnosis, because it is only in the hair that is growing during the time arsenic is being administered that excess of arsenic is stored, and when sufficient doses to produce tenesmus have been administered they will generally have been large, and therefore have been given over only a short period.

Besides arsenic, other irritant drugs may produce tenesmus, especially perhaps *cantharides*, *calomel* in repeated doses, *colocynth*, *gamboge*, and indeed most of the more powerful purgatives. The diagnosis depends upon a knowledge of the drugs that are being administered.

Rectal Conditions. There remain for discussion a number of other conditions which may produce painful and frequent but fruitless straining at stool, the cause being either irritation of the rectum or obstruction to it or within it. These may be enumerated as follows:

1. *Causes within the Lumen of the Rectum:*

Impacted feces	A foreign body that has been inserted	Concretions Worms.
----------------	---------------------------------------	-----------------------

2. *Things in the Wall of the Rectum:*

Carcinoma	Adenoma	Fissure
Rectal prolapse	Hemorrhoids, especially if thrombosed	Proctitis.
Polypus or polyp		

3. *Things Outside the Rectum:*

Enlarged prostate	Vesical calculus	Pelvic hamatocoele
Periprostatic abscess	Ovarian cyst	Ectopic gestation.
Periproctal abscess	Uterine fibroid	
Ischiorectal abscess	Retroverted gravid uterus	

The diagnosis of all the above depends upon careful examination of the anal region, the rectum, and the vagina, by inspection—direct, or through a speculum, proctoscope, or sigmoidoscope—or by palpation with the finger.

Impacted feces may, from their symptoms, simulate rectal carcinoma closely; but when there is carcinoma of the rectum one's finger when inserted seldom comes upon a mass of feces, whereas with fecal impaction the mass is generally well within reach of the finger. The diagnosis will be confirmed by removing the mass itself piecemeal with a spoon, followed by enemata or other local measures, after which the patient recovers completely.

Rectal concretions differ from impacted feces only in the material of which they are composed; for instance, instead of being ordinary fecal material they may consist of hard lumps of *bismuth*, *magnesium*, *chalk*, or other drug that has been given by the mouth, or of the husks or products of some unusual meal—as an example of which one may mention the case of a boy who, having stolen a bundle of cinnamon sticks, chewed them up and swallowed them, and a day or two afterwards suffered extremely from tenesmus as the result of a mass of undigested bits of cinnamon stick that had been impacted in his rectum. *Hair balls* have caused similar trouble, though they are even rarer in the rectum than they are in the stomach.

Adenomata, or long finger-shaped non-malignant polypi of the rectum, occur sometimes in such a way as to produce a kind of entanglement in which faeces become impacted higher up than the finger can reach, and the patient will be thought to be suffering from carcinoma of the sigmoid colon or of the pelvic colon : there will, however, as a rule be much less wasting than there would be with malignant disease, though both conditions produce their symptoms at a similar age. The diagnosis will depend upon examination with the proctoscope or the sigmoidoscope, and perhaps upon excision of such polypi as can be reached, followed by microscopical examination.

Another condition which may simulate rectal carcinoma very closely is *periproctal inflammation* followed by the formation of an abscess round the pelvic colon. The tenesmus which results, the constant painful straining, and the unsatisfactory evacuations may be associated with obvious ill health, anaemia from loss of sleep, and loss of weight : so that malignant disease will frequently be thought the almost certain diagnosis. The condition is by no means so easy to detect as might be supposed : sometimes it is not until the patient has been anaesthetized with a view to further examination with the proctoscope and sigmoidoscope that the nature of the condition is indicated by a sudden gush of pus escaping past the instrument as the result of the bursting of the abscess. The cause of such a condition is generally some previous local inflammation in the rectum, associated, for instance, with piles, or a polypus which has hitherto produced no symptoms at all : in some cases there may be both carcinoma and abscess, the latter the result of the former.

A *vesical calculus* causing tenesmus will generally be one situated in a pocket of the bladder posteriorly : it is a very rare cause of tenesmus, and generally there is or has been hæmaturia to indicate the need for examination of the bladder either with the sound or the cystoscope.

The remaining conditions in the above list need not be discussed in detail : they will be diagnosed by rectal or vaginal examination or by a combination of the two.

There remains still one other very important cause of tenesmus, namely, *tabes dorsalis with rectal crises*. The symptom is not so uncommon as might be supposed. Not a few cases of *tabes dorsalis* complain that they are unable to go about their duties as early in the morning as they would like, because after going to the closet in the ordinary way after breakfast they find that at intervals of perhaps half an hour they suffer from repeated urgent and painful re-calls, extending over perhaps two or three hours before the bowels settle down to comparative comfort for the rest of the day. Not much is passed after the first one or two visits to the closet, but the patient dares not be far away whilst the recurrent crises continue, for the call is urgent and very painful : but as a rule, after two or three hours of suffering of this kind he finds that he is free until the next day. The condition is quite distinct from the incontinence of faeces which may result at a later stage of the malady : it is an example of purely nervous tenesmus, which, however, may simulate carcinoma of the bowel. It may last for months or years, and then cease to trouble the patient spontaneously, just as the lightning pains of *tabes* may. The patient's complaint is generally of diarrhoea, but upon careful inquiry it is found that the diarrhoea in the sense of fluid evacuations is much less pronounced than the tenesmus—that is to say, the recurrent painful call to stool without material evacuation. The diagnosis depends upon detecting the absence of knee-jerks and the existence of Argyll Robertson pupils.

TESTES, ATROPHY OF.—(See ATROPHY, TESTICULAR, p. 85.)

TETANIC CONTRACTIONS.—(See CONTRACTIONS, p. 168.)

THERMO-ANÆSTHESIA.—(See SENSATION, SOME ABNORMALITIES OF, p. 747.)

THIRST, EXTREME. Cases of extreme thirst may be subdivided into two main groups : namely, those with and those without polyuria. To the former belong such conditions as diabetes mellitus, diabetes insipidus, and hysteria, which are discussed under **POLYURIA** (p. 652). To the other group belong such conditions as are for the most part so obvious as to require no more than simple enumeration as follows :—

1. Prolonged abstention from drinking : purposeful, or the result of necessity.
2. Fevers and febrile states.

3. Excessive loss of fluid : (a) From the skin by profuse perspirations, natural or pathological ; (b) From the stomach, from repeated vomiting ; (c) From the bowel, from excessive diarrhoea ; (d) Into serous membranes, as in acute peritonitis.

4. After severe hæmorrhage : (a) External, e.g., post-partum, hæmatemesis, hæmoptysis ; (b) Internal, e.g., from duodenal ulcer, ruptured tubal gestation, leaking aneurysm.

5. Gastrectasis due to pyloric stenosis, owing to the fact that the stomach absorbs little fluid as compared with the intestines.

6. Poisoning by such drugs as dry up the secretions of the mouth, notably belladonna and its allies, or astringents such as alum, gallic acid, tannic acid, or perchloride of iron.

7. The exhibition of excess of various salts, particularly sodium chloride, either as such, or incorporated in various food-stuffs.

8. The rapid accumulation of ordema fluid in the subcutaneous tissues : for instance, when extensive swelling of the legs occurs for the first time in a case of failing heart, there may be intense thirst for the first few subsequent days, until the patient develops a fresh balance of his tissue fluids.

It is clear that in some cases more than one factor at a time may be causing extreme thirst.

Herbert French.

THORACIC VARICOSE VEINS. (See VEINS, VARICOSE THORACIC, p. 910.)

THRILLS, PRECORDIAL. In order to arrive at a diagnosis of the cause of any thrill which is felt over the præcordia, two facts must first be ascertained, namely : (1) *The situation of the thrill* ; and (2) *Its rhythm*. Having discovered a thrill over the mitral area, that is, in the region of the apex beat, and found that it is presystolic in rhythm, it is obvious that it is due to *mitral stenosis*. The valvular lesion will be confirmed by the presence of a presystolic bruit, as it is rare to find the thrill without a bruit being associated with it. On the other hand, if the thrill be systolic in time, and *mitral regurgitation* be present, the thrill is due to this valvular lesion. A systolic thrill at the cardiac apex may also be caused by *pericardial friction fremitus*, or *pleuritic fremitus* : auscultation, and the relation of the thrill to respiratory movements, will serve to distinguish these from mitral valvular thrills.

A systolic thrill in the second right intercostal space close to the sternum may be due to *aortic stenosis*, *thickening of the aortic valve*, *atheroma*, or *dilatation* or *aneurysm* of the ascending portion of the thoracic aorta, and the diagnosis of the cause of the thrill can only be made by the other physical signs which indicate the morbid condition present. Thus, if there be dullness in the second right intercostal space, over which the thrill is felt, there is probably dilatation or aneurysm of the arch of the aorta. The likeliest cause of a pronounced systolic thrill to the right of the upper part of the sternum is aortic stenosis ; and it is dangerous to diagnose real aortic stenosis without this thrill, for many systolic bruits in the aortic area are due to minor changes in the aortic valves or in the aorta itself without any real stenosis.

A diastolic thrill may also be felt in the second right intercostal space close to the sternum, but it is rare ; when present, it is due to *aortic regurgitation*, and is accompanied by the characteristic diastolic bruit and water-hammer pulse. More often the thrill, like the bruit, is most marked in the third left space close to the sternum.

In the pulmonary area, viz., in the second left intercostal space near the sternum, systolic thrills are due to *congenital affections* of the heart, especially *pulmonary stenosis*, *patent interventricular septum*, and *patent ductus arteriosus*. An extensive thrill over the base of the heart in young children is nearly always due to congenital malformation. The apex beat is generally near its normal position. The cardiac dullness usually extends to the right of the sternum as the result of enlargement of the right ventricle, and there is commonly a loud universal systolic bruit, having its point of maximum intensity over the base of the heart to the left of the sternum— in the second space when there is pulmonary stenosis, in the second and third spaces with patent ductus arteriosus, and in the third and fourth spaces with patent interventricular septum. With pulmonary stenosis one expects cyanosis, either continuously present or occurring at intervals, dyspnoea, especially upon exertion, clubbing of the fingers and toes, and polycythæmia ; but with patent ductus

arteriosus, or with simple perforation of the interventricular septum, there may be no symptoms accompanying the abnormal physical signs.

Presystolic and systolic thrills sometimes, but very rarely, occur to the right of the sternum in the *tricuspid area*, due to *stenosis* and *incompetence* of this valve.

Herbert French.

THROAT, SORE. (See SORE THROAT, p. 757.)

THYROID GLAND ENLARGEMENT. An enlarged thyroid gland gives rise to a swelling in the front of the neck, internal to and under the sternomastoid muscles and internal to the carotid vessels, which, if the swelling is large enough, are pushed outwards. The gland is connected intimately with the larynx so that it rises and falls with the larynx and trachea during deglutition. This sign alone is generally sufficient to establish the diagnosis of enlarged thyroid gland, but there are two sources of fallacy: (1) A swelling not thyroid in origin but lying above it or in front of it, such as a subhyoid bursa or sebaceous cyst, or a suppurative or syphilitic perichondritis of the thyroid cartilage, may present the same sign: (2) A thyroid swelling, if fixed, as it may be by inflammation or malignant growth, may not present it. In most cases, however, a swelling in the position of the thyroid gland which moves on deglutition indicates an enlargement of that gland.

Varieties of Enlargement and their Differential Diagnosis. During *menstruation* and *pregnancy* the thyroid becomes enlarged, but seldom sufficiently so to cause symptoms: if the gland happens to be the seat of pre-existing disease the increase of swelling may be sufficient to induce respiratory difficulty.

Parenchymatous Goitre, or a general hypertrophy affecting the whole gland, is the commonest form of enlargement. All parts of the gland are affected more or less equally: the tumour being bilateral, the normal shape is preserved. The swelling is freely movable, painless, and soft. It is rarely congenital, and more often appears about puberty. Its rate of growth is usually very slow, and it may attain an enormous size without causing any other symptoms. Where simple parenchymatous goitre ends and Graves' disease begins it is difficult to say, for that which is a simple thyroid overgrowth at one time without any collateral symptoms may later become associated with typical Graves' disease phenomena.

Cystic Goitre is a loose term used to cover any form of enlargement of the thyroid which is caused chiefly by the presence of one or more cysts. If the cyst is large and lax fluctuation may be made out. The cysts, however, are often small and tense, and difficult to distinguish from solid adenomata. Cysts are rarely present without some enlargement of the rest of the gland.

Adenomatous Goitre. The common cause of unilateral enlargement is the presence of an adenoma, a definite encapsuled tumour which may contain cysts and grow to a large size. A hæmorrhage into one of these cysts may cause a very rapid enlargement, and so give rise to a suspicion of malignancy: cases have even been reported in which an intra-cystic hæmorrhage has been followed by acute dyspnoea and death. Adenomata may be single or multiple: when present in both lobes the enlargement may be difficult to distinguish from the parenchymatous form.

Fibrous or Ligneous Goitre is a rare condition, due to a primary chronic inflammation of the whole gland, and resulting in a firm dense enlargement.

Carcinoma is not often met with. It occurs with equal frequency in both sexes, and is rarely seen before the age of forty. In the early stages, while still confined within the capsule of the gland, it may be difficult to differentiate from the other forms of goitre. It should be recognized by its rapid growth, its hardness, and irregular bossy outline. When the neoplasm has penetrated the capsule and invaded surrounding structures the diagnosis has become obvious. The tumour may become fixed, no longer moving on deglutition: often one or other vocal cord is paralysed, a condition rarely seen with innocent goitre: and involvement and ulceration of the trachea are common. The cervical lymphatic glands may be enlarged, but as those first implicated are placed deeply, defying detection, not much help is gained from this source. There is a special liability for metastatic secondary deposits to occur in bones, particularly in the vertebrae and cranium.

Exophthalmic Goitre (Graves' disease, von Basedow's disease) is far more common in girls and women than in men (*Fig. 247*, p. 292), and rarely occurs before puberty or

after middle life. The most prominent features of the disease are : (1) Exophthalmos ; (2) Tachycardia with palpitation ; (3) Enlargement of the thyroid gland, often pulsatile ; (4) Tremulousness of the hands and general nervous excitability ; (5) Breathlessness on exertion. The vision is normal, but when the eyeball is moved downwards the upper lid does not follow as in health (von Graefe's sign). The palpebral aperture is wider than in health, owing to retraction of the upper and lower lids (Stellwag's or Dalrymple's sign). Pigmentation of the skin may be intense (*Fig. 504*, p. 643) and simulate Addison's disease, but the mucous membrane of the mouth is not affected as in the latter malady. There is often great enlargement of the thymus gland in Graves' disease cases, clinical evidence of the fact being afforded sometimes by the X rays (*Fig. 213*, p. 248).

A well-marked case is quite characteristic, but there are others extremely hard to separate from simple parenchymatous enlargement, for with this, especially in young girls, anemia is often associated, and with it the symptoms of tachycardia, palpitation, and breathlessness. It often becomes a matter of opinion whether a given case should be styled simple parenchymatous goitre or incipient Graves' disease. Some authorities differentiate Graves' disease into various types, of which two are clearer than the rest. These are : (1) True exophthalmic goitre, with general hypertrophy of the whole thyroid gland, including the isthmus ; (2) Toxic adenomatous Graves' disease, in which the enlargement of the thyroid gland is uneven, and often only slight, one or more adenomatous masses being palpable on one side or the other ; in both conditions there may be tachycardia, exophthalmos, and tremor, but the variability in these classical symptoms is greater in the toxic adenomatous type of the malady than it is in the simple thyroid hypertrophy variety.

The above are the commonest forms of enlargement. Others much rarer are : *Enlargement due to pyogenic infection*, either acute or chronic ; in pyemia the thyroid may be the seat of multiple abscesses. *Tuberculous and gummatous disease* may also cause enlargement, and a slight degree of goitre has been noted in *typhoid fever, acute rheumatism, malaria, variola, cholera, and secondary syphilis*. *Hydatid cysts* of the thyroid gland have been noted on a few occasions. Simple hypertrophy of the gland, even to the extent of simulating Graves' disease, may result from long-continued *mental strain, fear, or fright* ; and from certain debilitating infections, such as *trench fever*.

Pressure Signs.—It having been ascertained that the swelling in the neck is definitely thyroid in origin and its nature defined, it remains to note whether there are pressure signs on the surrounding structures.

Pressure on the Trachea. Dyspnoea is one of the symptoms that may be produced by enlargement of the thyroid gland. It may be the only thing complained of by a patient not even aware of the presence of a goitre. The size apparently is not so important as the shape and situation, for one reaching to the waist may cause no obstruction, and one the size of a cherry, if situated between the sternum and trachea, may give rise to intense dyspnoea. If the goitre is unilateral the trachea is pushed over towards the opposite side and flattened ; if bilateral, as in the parenchymatous form, it is compressed laterally. The dyspnoea may be constant and distressing, or only noticeable on exercise or on lying down. Most of these patients like to lie high in bed, propped up on pillows.

Pressure on Nerves. Unless malignant, a goitre rarely causes much pressure on nerves. Those that may be involved are : (a) The recurrent laryngeal, resulting in paralysis of one or both vocal cords and alteration in voice, brassy cough, or stridor ; (b) The cervical sympathetic, shown by contraction of the pupil on the affected side and ptosis ; (c) The vagus ; (d) Rarely the nerves of the brachial and cervical plexuses. If any of these nerves are involved suspicion must arise as to the malignancy of the tumour.

Pressure on the Œsophagus. Being placed behind the trachea, the Œsophagus generally escapes pressure by a goitre, though this is to be remembered as a rare cause of dysphagia.

Pressure on Veins is common, particularly on the internal, external, and anterior jugulars. The pressure is rarely more than sufficient to make them stand out prominently.

George E. Gask.

TINEA, VARIETIES OF. (See FUNGOUS AFFECTIONS OF THE SKIN, p. 309.)

TINNITUS is a symptom which occurs in a large proportion of cases of disease of the ear, and occasionally when there is no obvious lesion of the auditory mechanism. The sounds complained of are usually subjective, but they may occasionally have an objective

origin. Tinnitus may be continuous or intermittent. Its intensity and character vary greatly in different patients : to some it is an intolerable annoyance, and occasionally has even been the cause of suicide. The character of the sound may give some clue to the cause. Thus a pulsatile or rhythmical sound may be produced by the flow of blood through an atheromatous internal carotid artery, which in its course through the carotid canal is separated from the tympanum only by a thin plate of bone. The symptom is common in cases of atheroma, arteriosclerosis, plethora, granular kidney, especially if there is a high blood-pressure ; it may also be a great trouble when there is severe anæmia, especially in pernicious anæmia. A creaking noise may be produced by cerumen, or a foreign body, in the external auditory meatus. A bubbling noise may be due to the presence of catarrhal exudation in the middle ear. A cracking or clicking sound may be caused by spasmodic contraction of the dilatator tubæ and salpingopharyngeus muscles which are attached to the Eustachian tube. When the character of the sound is described as humming, hissing, roaring, whistling, or musical, it is practically always subjective, and due to some irritation of the auditory nerve, usually at its terminations in the labyrinth. In rare cases the tinnitus may be associated with an intracranial murmur which can be detected on examination of the head with the stethoscope. An audible intracranial murmur associated with tinnitus may be due to the following causes : (1) Possibly venous murmurs associated with increased intravenous pressure due to excessive pulsation of the brain ; (2) A *bruit de diable* in the jugular bulb which may occur in anæmia, plumbism, syphilis, cachexia ; (3) Intracranial aneurysm. The sudden explosive sounds in the insane and others may be due to similar causes.

A distinction must be made between tinnitus and hallucinations of hearing, the latter usually taking the form of hearing voices, and indicating mental trouble, usually of a serious nature. Tinnitus, however caused, is usually influenced markedly by the general health and environment of the patient. Thus, sometimes the noises are less marked when the patient is in the open air, when his attention is occupied by other matters, or when the sense of hearing is occupied by listening to objective noises. Similarly, the trouble may be present only at night, but may appear in the day-time if the patient closes the external auditory meatus with his finger. Generally speaking, tinnitus becomes less marked and more bearable when the general health of the patient is good, and increases when the sufferer is out of health or overworked, either mentally or physically. Working in close, stuffy rooms, or in proximity to noisy machinery, over-indulgence in alcohol, and excessive smoking, have a bad effect ; in women the trouble may be increased during pregnancy, menstruation, or the menopause. Toxic gases are apt to cause tinnitus temporarily if it is a question merely of staying too long in a stuffy room, persistently if the conditions of life lead to the inhalation of such things as small quantities of coal gas escaping from a leaky gas-pipe, or the exhaust gases from engines or motor-cars for instance, in the cabin of a motor-boat, or in a bedroom over a garage. Severe tinnitus, with or without vertigo, may be due in a similar way to the effects of gases or fumes inhaled in the course of occupation in certain trades in which, for instance, carbon bisulphide, seleniuretted hydrogen, sulphuretted hydrogen, or other unusual chemicals are employed in solvents ; in a recent case lacquering tables as a hobby was the cause.

Rapid changes of atmospheric pressure may cause tinnitus rising to heights, for instance in an aeroplane, or going to depths, as amongst miners or divers.

Though tinnitus is very common in diseases of the ear, yet serious lesions of the middle ear, internal ear, or auditory nerve may be present without this symptom. There is no constant relation between tinnitus and deafness. The former may be present with perfect hearing, but when long continued the hearing nearly always becomes impaired. The sounds, too, may persist when the patient has become totally deaf.

Tinnitus may occur from the following diseases of the ear :—

1. The presence of *cerumen*, *aural polypi*, or a *foreign body* in the external auditory meatus. Removal of the offending body will in this case probably lead to the cessation of the tinnitus.

2. In any *inflammatory disease, acute or chronic, suppurative or non-suppurative, of the middle ear*. In catarrhal inflammation of the middle ear, the noise frequently has the character of bursting bubbles, and is due to movements of the viscid exudation in the

itself. In *otosclerosis*, tinnitus is a very prominent and usually early symptom. It may occur before any alteration in hearing is present.

3. In diseases of the *internal ear* tinnitus is especially liable to occur in a severe and intractable form. Thus it is especially likely to be present in *Ménière's disease*, *syphilitic disease* of the internal ear, and in those lesions of the internal ear which may arise in the course of *typhoid* and other *specific fevers*. *Extension of suppuration to the labyrinth* from the middle ear is also an important cause; and it may be present, usually associated with deafness, after a *fracture of the base of the skull*.

Persistent unilateral tinnitus with progressive internal-ear deafness and vertigo must raise a suspicion of *acoustic nerve tumour*.

'Noises in the ears' may be complained of in a considerable number of general diseases, either with or without a lesion of the ear. Thus, they are frequently present in *anæmia*, and in diseases such as *leukæmia* or *pernicious anæmia*, in which anæmia is a prominent symptom.

Some *cardiac lesion*, especially aortic regurgitation, may be found in the pulsatile variety of tinnitus. *Gout*, *chronic nephritis*, *uræmia*, and *arteriosclerosis* with high blood-pressure, may also be responsible for tinnitus, and it may occur during attacks of *migraine*. Sometimes it has apparently a reflex origin, being associated with neuralgia or digestive disturbances, especially dyspepsia. *Malaria* may also be a cause, though here the trouble is likely to be the result of large doses of *quinine*. Other drugs likely to cause the trouble are *salicylates*, *antipyrin*, the excessive use of *tobacco*, and after *anæsthetics* such as chloroform or ether.

In persons who constantly use the telephone tinnitus may occur, associated with pain and some deafness—a condition known as 'telephone ear'. Herbert French.

TONGUE, PAIN IN. (See PAIN IN THE TONGUE, p. 590.)

TONGUE, SORE. (See PAIN IN THE TONGUE, p. 590.)

TONGUE, SWELLING OF. (See SWELLING OF THE TONGUE, p. 851.)

TONGUE, ULCERATION OF. (See ULCERATION OF THE TONGUE, p. 895.)

TREMOR occurs when the normally continuous contractions of a muscle at work, or the normally uniform tone of a muscle at rest, are replaced by a succession of separately perceptible muscular twitches. In these circumstances a movement which is normally uniform becomes tremulous: a position that can be maintained steadily under normal conditions is now kept unsteadily or shakily.

Tremors are of very various periods, amplitudes, and general characters in different cases. Their physiology and pathology are not at present fully understood, so that it is not yet possible to classify them etiologically. From a clinical point of view they may be classified roughly in accordance with their more obvious physical characteristics—their fineness, periodicity, regularity, and the circumstances that favour or inhibit their production: but an unbroken series of graduated tremors can be traced in various diseases, passing by imperceptible degrees from the rapid and minute oscillations observed in paralysis agitans to the coarse and irregular movements composing the intention-tremor of disseminated sclerosis. A similar variety of regular tremors may be observed sometimes in a normal person as the temperature of his body falls from exposure to cold, or during the occurrence of a rigor. Hence a rigid clinical classification of tremors is impossible.

CLASSIFICATION.

Fine Tremor.

Exposure to cold	Post-encephalitic	Parkinson-	Tobacco	Mercury
Nervousness, emo-	ism	ism	Absinthe	Lead
tion	Paralysis agitans		Morphia	Manganese
Muscular fatigue or	General paralysis of the in-		High pyrexia	
weakness	sane		Hysteria	
Convalescence	Graves' disease		Neurasthenia	
Congenital and fam-	Occupation neurosis		Railway spine	
ilial tremor	Chronic intoxications, e.g., by		Uremia.	
Senile tremor	Alcohol	Cocaine		

Unilateral Fine Tremor.—

Cerebral tumour	Chronic hemiplegia	Hysteria.
-----------------	--------------------	-----------

Coarse Tremor.—

Exaggerated degrees of fine tremors	Familial and hereditary ataxias	Chronic hemiplegia Chorea.
--	------------------------------------	-------------------------------

Intention Tremor.—

Disseminated sclero- sis	Hysteria Congenital cerebral diplegia	Some cerebral or cerebellar lesions.
-----------------------------	--	---

FINE TREMOR.

Fine tremor consists of regular oscillations of small amplitude due to alternating contractions in antagonistic muscles or groups of muscles, repeated from three to nine times per second. It is usually most marked in the extremities, but may also as in old age and in paralysis agitans affect the head and neck. It may occur only when some movement is attempted; or it may continue also when the patient is at rest. Fine tremors cease almost invariably during sleep; emotion habitually increases them. They are not purposive, and should be distinguished from the fibrillar contractions (see CONTRACTIONS, p. 168) of individual muscle-fibres or muscle-bundles seen in some muscular degenerations.

Fine tremors occurring in consequence of *cold, nervousness, excessive emotion, convalescence*, and *muscular fatigue* or *weakness*, are matters of common daily observation. They tend to pass off as the patient's condition of mind or body improves, and should occasion little trouble in diagnosis.

Congenital and familial fine tremors occur mostly in children or young adults, mainly in the hands and arms, face, or tongue. The oscillations are often absent while the patient is at rest, but make their appearance whenever movement is attempted, and are increased by nervousness or emotion. They can often be suppressed for a time by a strong effort of the will, and in many instances they disappear as the patient grows older. They cause practically no inconvenience, and are not accompanied by any other abnormalities in the neuromuscular apparatus. Their diagnosis should be made plain by the patient's personal and family histories.

Senile tremor and paralysis agitans may be considered together. Senile tremor comes on with old age in the form of fine regular or irregular oscillations affecting the arms and the head. Both sides of the body are involved, the head early, and the tremor ceases during repose and in sleep. The muscles of the affected parts are neither rigid nor weak. These senile tremors must be distinguished carefully from the tremors of paralysis agitans, or Parkinson's disease—a progressive and more serious disorder: in this the tremors are of several varieties. A fine oscillatory to-and-fro tremor, with from three to six excursions per second, affects the extremities and head in some cases. In others, the tremor is coarser, rhythmical, slower, and to some extent purposive: in typical instances it produces the alternating movements in the thumb and index finger described as 'bread-crumbling' or 'cigarette-rolling'. These may be combined with more irregular movements of flexion and extension at the wrist, pronation and supination of the forearm. The progressive development of these tremors and movements is often characteristic: almost invariably they affect one half of the body before the other, beginning in one hand, spreading to the leg of the same side, and, after an interval of months or years, involving the opposite limb in a similar manner. As a rule, the movements continue when the patient is sitting or lying at rest; in severe cases they may persist even during sleep. In most instances they can be lessened by an effort of the will, and diminish also on passive or voluntary movement. If, on the other hand, they increase on voluntary movement, a tolerable imitation of an intention tremor may result. They are augmented by emotion or excitement. In cases of some duration a well-marked coarse shaking of the arms may be a noticeable feature, while contractions alternating in the flexor and extensor muscles of the legs may cause the feet to clatter when they are placed on the floor; the thighs are commonly held in adduction. The tremor in *post-encephalitic Parkinsonism* closely resembles that of paralysis agitans, and is generally accompanied by the rigidity characteristic of that disease.

Paralysis agitans is characterized by other signs that facilitate its diagnosis, and the chief of these are: (a) *Muscular rigidity*, causing a fixed, expressionless facial aspect, (see FACHS, p. 292), a monotonous voice, a bent and rigid carriage, and a shuffling, hesitating gait, with festination, propulsion, and retropulsion. Festination implies that the patient, in walking from one point to another, starts with slowness and difficulty, but accelerates as he goes along, much as if he were running after his own centre of gravity, and at the end he may even fall forwards unless there is some object at hand for him to catch hold of. Propulsion, retropulsion, and the rarely observed lateropulsion, are terms meaning that the patient, sent off with a vigorous push to walk forwards, backwards, or sideways, exhibits the same acceleration and proclivity to fall down at the end forwards, backwards, or sideways. (b) *Muscular weakness* of the tremulous or rigid parts. (c) *Paræsthesiæ*, such as aching pains about the limbs or body, flushes of heat or cold. The sphincters and mental faculties are not affected, while the deep reflexes are usually normal, but may be increased. Cases of Parkinson's disease occur in which tremor is absent: the presence of the other signs mentioned above, however, should suffice for its recognition. *Bilateral cortical degeneration*, with its slowly increasing rigidity and muscular weakness and its set facial expression, may resemble paralysis agitans: but it is accompanied by progressive mental failure, increase of the deep reflexes, and sphincter troubles.

The tremor of certain types of *general paralysis of the insane* is a fine, irregular oscillation, often with a twitching character. It first appears about the lips and tongue, often associated with some blurring of articulation, and later spreads to the hands. For the most part this tremor occurs on exertion: it varies in extent, and may almost disappear during periods of general improvement. In the later stages of the disease a coarse universal tremor sets in, combined, perhaps, with grinding of the teeth. In these patients the moral and intellectual changes, tottering gait, alterations in the tendon- and pupil-reflexes, and other phenomena of general paralysis, will probably not escape attention.

In *Graves' disease* a fine, regular, and rapid tremor, about eight to the second, on exertion, is one of the cardinal signs. It affects the outstretched fingers most, the hands and arms much less, and least often the legs: it is increased by movement or by excitement. In addition, attacks of trembling that affect the whole body may occur. It is only in aggravated cases, however, that these tremors are so severe as to interfere with the customary employments of the hands. The tremors of Graves' disease are likely to be associated with thyroid enlargement, exophthalmos and the other ocular phenomena, tachycardia, attacks of palpitation, wasting, sweating, or mental changes, so that the diagnosis ought not to be difficult.

Fine tremors are observed frequently in many of the *chronic intoxications*, particularly those due to alcohol, absinthe, lead, mercury, manganese, antimony, nicotine, carbon bisulphide, morphine, cocaine, and certain other organic compounds that may be taken into the system in the course of modern trade processes which involve the use of complex solvents, reagents, or dyes. *Alcoholic tremor* is fine, regular, and rapid: it is well shown in the outspread fingers of the extended hand and in the feet. In many cases it can be felt by the observer's hand more readily than it can be perceived by his eye: or it may be rendered more conspicuous by laying a sheet of paper on the backs of the outspread pronated fingers and hand. It is absent during rest, and is increased by movement, excitement, or fatigue. It may also affect the tongue, lips, and facial muscles, taking the form of a rapid and rather irregular twitching, increased on exertion. This tremor is an early sign of alcoholism, and is often more marked in the morning hours, when it is due, perhaps, to fatigue and want of alcoholic stimulation: it can be controlled to some extent by the will. Associated with it is a certain general nervousness and jumpiness: in addition, the patient will no doubt exhibit some of the other signs of chronic alcoholism – venous stigmata or acne rosacea on the nose and face, restlessness, insomnia, gastric disturbances – particularly the morning vomiting of mucus on an empty stomach, and loose motions – paræsthesia and weakness of the extremities, mental and moral deterioration. If the main facts of the case can be made out, tremors due to alcoholism should not be hard to diagnose. A history of chronic alcoholism should always be inquired after most carefully, both from the patient, who may deny it *in toto*, and from the patient's friends, who may hasten to admit more than the facts warrant. This is of importance, because mere *nervousness* at the prospect or realization of an interview with a medical

man will often bring on a fine but temporary tremor, indistinguishable, for the time being, from the lasting fine tremor of the drinker. If such a tremulous, but teetotal, patient has indigestion and acne rosacea, and repudiates any veiled suggestion of alcoholism with apparently unnecessary warmth, there is some danger lest these evidences be taken as confirming the erroneous diagnosis of alcoholism.

The tremor of *mercurial poisoning*, a very rare complaint nowadays, is at first fine, but later coarse and even choreiform. It is met with amongst workers in furs, hat-makers, and others who use skins that have been cured with mercurial compounds. It begins in the face, hands, and arms, and may spread to all parts of the body. At first it is brought out only by excitement, or on attempted movement. Later, it may persist even during sleep, and speech may be interfered with from involvement of the muscles of the tongue, pharynx, and larynx. Other prominent symptoms of mercurialism that should not be absent are profuse salivation, stomatitis, anemia, and cerebral symptoms of various kinds. Mercurial tremors may have to be diagnosed from those of paralysis agitans or disseminated sclerosis.

In *lead poisoning* a fine tremor of the affected limb is sometimes met with in cases marked by paralysis. The oscillations may also be seen in the tongue and lips, particularly in the rarer instances of chronic plumbism that exhibit cerebral symptoms and simulate general paralysis of the insane. The diagnosis of these unusual cases would be difficult unless a suspicion of lead poisoning were aroused, either by a history of exposure to the intoxication, or by the occurrence of other signs and symptoms of plumbism (see p. 45).

Manganese tremors are met with mainly in those who have worked in manganese mines: there may be coarse tremors of hands only, or of hands, arms, feet, and legs, increased by attempts at voluntary movement: more often there are also nystagmus, ataxy, changes in the reflexes and in the intellectual faculties indicative of gross changes in the central nervous system. Tremors due to *antimony* are similar to those caused by manganese, and their nature will be suggested by the patient's occupation.

In *hysteria* the clinical picture of any or every disorder of movement or sensation may be more or less closely reproduced: and tremors of every variety may be met with in hysterical patients. The diagnosis may be extremely difficult until hysteria is suspected, when it may be confirmed by the discovery of signs and symptoms that, singly or together, are pathognomonic (p. 570). The diagnosis of hysteria should never be made lightly or without finding some cause for its presence. It is as important to discover the psychopathology of a hysterical symptom as it is to determine the morbid process at work in a case of organic disease.

Unilateral Fine Tremor is but rarely seen. It may be a *hysterical* manifestation, functional, or may be significant of an underlying lesion of the central nervous system. Unilateral tremor may occur in *tumour of the frontal region of the brain*: if present, it occurs in both arm and leg, and only on the same side of the body as the tumour. The patients will often exhibit mental changes, such as inattention, incoherence, loss of memory, alterations in character: sometimes, too, irritative phenomena occur.

Unilateral fine tremor may develop on either the same or the opposite side of the body in a case of *tumour of the mid-brain and sub-thalamic region*. The general symptoms of cerebral tumour will be present, and in addition certain localizing signs may make their appearance. The chief of these would be paralysis of the third nerve, loss of sensibility over the area supplied by the fifth nerve, eccentric position of the pupil, defective reaction of the pupil to light, and weakness of the upward movements of the eyeballs.

It may be added that fine tremors occasionally occur in the paretic limbs after *hemiplegia*. The history of the case and the presence of other signs characteristic of hemiplegia should make the diagnosis here a comparatively straightforward matter. Fine tremor may be seen in *chorea*, and may be unilateral in such cases.

COARSE TREMOR.

Coarse tremors may develop as temporary exaggerations or later developments of the fine tremors occurring in several of the morbid states already considered. Thus, when the body is thoroughly chilled or fatigued, or when a patient is in a rigor, the initial fine tremor will often pass on into a very coarse tremor, as the amplitude of the involuntary

muscular contractions increases, their rhythm remaining much the same. The fine tremor of paralysis agitans or general paralysis may similarly grow into a coarse tremor; coarse tremors are seen not infrequently in hysteria. The diagnosis in all these cases must be made on the lines already indicated.

Coarse tremor is met with sometimes in the various forms of familial and hereditary ataxia. Thus in *Friedreich's disease* (p. 624), in addition to intention tremor, irregular involuntary motions, described as coarse tremors in some cases, as choreiform in others, take place in the arms while the patient is at rest. Irregular nodding or tremulous movements of the head and trunk also occur in advanced cases; the muscles of articulation and of the face may exhibit irregular purposeless contractions or quiverings when conversation is attempted. In *spinocerebellar ataxia*, irregular choreiform movements, or constant tremors, large and small, may be seen in the head, trunk, and limbs whenever the attempt is made to hold them steady, but unsupported. Similar disturbances have been recorded in *cerebellar ataxia* and in the *olivo-ponto-cerebellar atrophy* of Dejerine and Thomas. In all these conditions the ataxia is the prominent symptom, the coarse tremor being no more than an occasional epiphenomenon; the diagnosis between them must be sought in special manuals, and also under the heading ATAXY (p. 73).

The coarse tremor of the affected limbs seen in patients with chronic or spastic *hemiplegia* or *diplegia*, and in some other cerebral disorders, is a variant of the athetoid or choreiform movements that are characteristic of those conditions. They are considered under the heading CONTRACTIONS (*Paramyoclonus multiplex*, p. 174). It is practically impossible to draw any hard-and-fast line between the grosser fine tremors and the finer coarse tremors. In the same way, coarse tremors merge insensibly into the lesser degrees of athetotic and choreiform convulsions.

INTENTION TREMOR.

Intention tremor known also as *action* or *volitional tremor* has been defined as tremor produced, or if not produced at least exaggerated, by voluntary movements. These tremors affect the upper extremities, and sometimes the head and trunk also; the limb is quiet when not in actual use, but as soon as voluntary movement is attempted irregular and involuntary to-and-fro motions begin in it, and are superadded to the intended movement. These to-and-fro motions become more marked, and sometimes more rapid, the more nearly achievement of the desired movement is reached. The greater the amount of precision demanded by the voluntary action, the greater becomes the amplitude of these involuntary excursions. Wishing to drink, the patient may lift the cup from the table steadily enough; but as the cup approaches his lip, the involuntary movements appear and rapidly increase till the contents are jerked wildly in all directions as it reaches his mouth. The tremor may spread from the muscles that are being put into action and cause extensive jerky movements of the head and trunk. Intention tremor is often present in cases of *disseminated sclerosis*. The arms are affected most frequently, but careful observation will often show that none of the voluntary muscles escape. The head may oscillate when the patient is holding it up; the trunk may exhibit jerky movements when he sits or stands; the legs when he stands or walks, after the disease has made some progress. Disseminated sclerosis is a protean disorder. Typical examples, however, may be recognized by the occurrence of intention tremor (*Fig. 661*) muscular rigidity, nystagmus, pallor of the optic discs, and staccato or scanning speech. The deep reflexes are increased; the gait is spastic or ataxic; Babinski's sign is present; subjective sensory signs are far commoner than objective; and control over the sphincters may

Fig. 661. Movements in intention tremor.

Fig. 662. Movements in ataxia.

The dotted lines show the direction of the movement attempted.

sometimes be impaired fairly early in the disease, though as a rule their involvement comes on late. The diagnosis of disseminated sclerosis, however, does not depend upon the presence or absence of any particular sign or symptom, but upon a careful and detailed history; this will indicate the occurrence of lesions in different parts of the central nervous system at various intervals of time. In *hysteria*, intention tremor may occur in just the same way as a fine or a coarse tremor may; and other points of correspondence between hysteria and disseminated sclerosis may often be found in the age and sex of the patient, in the remittent course pursued by either of the disorders, in the frequent occurrence and partial recovery of various paralyses and of amblyopia with contraction of the visual fields, and in exaggeration of the deep reflexes. But distinct differences between the two are, fortunately, not wanting. In hysteria, the objective sensory signs are well marked, the optic discs are not affected, nystagmus is absent, Babinski's sign never occurs, and control over the sphincters is not lost. Attention to these points should suffice to clear up the diagnosis between hysteria and disseminated sclerosis; but in the earliest stages of the latter it may be necessary to keep the patient under observation for some little time before a definite opinion can be pronounced.

An intention tremor is not very rare in the *familial* and *hereditary ataxias*, especially Friedreich's disease and cerebellar ataxy; but the disturbance of movement in these disorders is characteristically an ATAXY (p. 73). It also occurs in some cases of *congenital* or *acquired cerebral diplegia* of backward or mentally defective children, occasionally appearing as a familial disease, and characterized by bilateral spastic paralysis affecting the limbs, or limbs and body. It is athetosis that is characteristic of these cases; but disordered movements of all sorts occur in them. In addition, the sphincters are commonly affected, the deep reflexes are increased, optic atrophy or inequality of the pupils is frequent; and if the patient is able to get about, a spastic or 'scissor' cross-legged gait is to be seen. Congenital cerebral diplegia in which the spastic weakness is most marked in the legs is described as *Little's disease*. The intention tremor occurring in birth palsy or in infantile hemiplegia has, unfortunately enough, been described under the name *choræa spastica*.

Intention tremor has also been recorded in a few instances of lesion of the *superior cerebellar peduncle*, *corpora quadrigemina*, or *optic thalamus*, particularly when the tegmentum, red nucleus, and rubrospinal tract are involved. It may be noted in patients with *extracerebellar tumours* growing in connection with the eighth nerve, and occupying the posterior fossa of the skull between the pons and cerebellum. It is seen in a certain proportion of cases of cerebellar atrophy, whether the degeneration is primary parenchymatous, progressive and due to interstitial and vascular lesions, or acute and following some acute specific fever. Intention tremor is also present in some patients with *olivoponto-cerebellar atrophy*. The diagnosis of these rare instances will naturally depend upon the development of other general and localizing signs of the intracranial disease.

E. Farquhar Buzzard.

TRISMUS, or lockjaw, signifies a maintained closure of the jaws by tonic muscular spasm so that the mouth cannot be opened. It is seen best in tetanus. The term does not include mechanical inability to open the jaws owing to such affections as mumps, alveolar abscess with surrounding inflammatory oedema, angina Ludovici, quinsy or severe tonsillitis, an odontoma, epithelioma of the mouth, myositis ossificans, and so forth; but there are at least two mechanical conditions that may not at first sight be obvious, but which may lock the jaws together and simulate true trismus—*impaction of a wisdom tooth*, and *arthritic changes in the temporo-maxillary joint*. These will be diagnosed as the result of a careful local examination of the teeth and of the joint respectively; in the latter case there may be osteo-arthritic changes in other joints also. X-ray examination may be required to detect the joint changes or the impacted wisdom tooth (*Fig. 663*).

Circumstantial evidence will generally serve to distinguish trismus due to *hysteria* or to *facial neuralgia*; and if there is any doubt at first this will disappear if the patient can be watched for a while. If there are convulsive seizures in a hysterical patient with trismus they can generally be distinguished from those due to tetanus or to strychnine poisoning by their polymorphous character, and by the fact that touching the patient, and other similar stimulation, does not bring them on so certainly as would be the case with strychnine or tetanus.

The rigidity of the face muscles in certain cases of *tuberculous* or *posterior basal* or

cerebrospinal meningitis never occurs by itself, and is a minor symptom amongst others that point to the correct diagnosis. The same applies to *epilepsy* and to *uræmia*.

Exceptionally, trismus may be met with in the course of severe general toxæmias : in *typhoid fever*, for instance, or *cholera* ; or *septicæmia*. The nature of the illness will have been diagnosed before the trismus sets in, and the symptom in these cases is quite an adventitious phenomenon.

Malingering may sometimes take the form of lockjaw, and it may be a little while before the fraud can be detected : sleep is sure to come in time, and as the result of fatigue the malingerer's muscles relax completely.

Catalepsy may include trismus amongst its varieties of maintained muscular contractions : the general mental symptoms will assist the diagnosis, and as a rule there are no convulsive seizures.

Trichinosis is very rare nowadays, but if infected pork is eaten raw, or insufficiently cooked, the larvae of the parasites find their way to many different muscles, and they show some predilection for those of the tongue, mouth, and jaws. The resultant irritation, pain, and stiffness cause trismus whose nature may be difficult to determine unless the history points to pork as the origin. The patient is very ill in the earlier stages, with high fever, and the condition is often fatal. There may be an epidemic of the malady. The blood exhibits eosinophilia. The final criterion of the diagnosis is the discovery of the typical parasites coiled up in their little oval cysts amongst the affected muscle fibres. In a certain proportion of acute cases it has been stated that the embryos can be detected in films prepared from the centrifugized deposit from 5 c.c. of the patient's blood after the red corpuscles have been laked.

Hydrophobia and **Tetany** seldom exhibit trismus as a prominent symptom. The former, though it is almost unknown in Great Britain now, would suggest itself if any convulsive illness developed after a definite bite by a dog, wolf, or other similar animal, particularly if the spasmodic muscular difficulty was markedly increased by efforts at swallowing. The symptoms may not develop for weeks or months after the bite, so that the patient may fall ill when he has come home after being bitten abroad. *Tetany*, also rare, is at once distinguished by its typical carpo-pedal contractions (*Fig. 1*, p. 2) ; trismus, almost constant in tetanus, is nearly always absent in tetany.

Strychnine poisoning gives rise to generalized twitchings and convulsions long before trismus, the lateness of the development of the latter serving to distinguish it from tetanus. There may be evidence of strychnine having been taken or administered, either by the mouth or hypodermically : the symptoms develop very acutely, and are apt to be rapidly fatal.

Tetanus is the cause *par excellence* of trismus : the diagnosis is often obvious if the illness develops steadily in an otherwise healthy person or new-born infant, starting with stiffness of the neck muscles, spreading to those of the face and jaw, and thence to the rest of the trunk and limbs, with a tendency to extremely painful exacerbations on the slightest stimulation, even by a stroke with a feather or the banging of a door : risus sardonicus : opisthotonos : no complete relaxation of the stiffening muscles unless chloroform is given : a duration of days rather than hours, and a termination in death more often than in recovery : especially if all these things follow a few days, or a week or more, after infection of the umbilical cord or a small penetrating wound with a rusty nail, a piece of stick, or other similar body that may have been contaminated with tetanus bacilli from the soil. It may be possible to demonstrate the presence of the drum-stick bacilli in films prepared from the deeper parts of the wound. The chief difficulty arises when there is no clear history, or when the wound has been so small that it has healed or cannot be found. Even then, most cases are so typical that they can be

Fig. 663. Skilagram showing an impacted lower wisdom tooth, to which the arrow points. (*Fig. Dr. W. H. Colquhll.*)

diagnosed as tetanus without much difficulty. Unnecessary anxiety arises chiefly in cases of impacted wisdom teeth, or of hysteria, where tetanus may be suspected at first; the subsequent course of the malady soon serves to exclude this.

Trismus may be simulated by *sclerodermia* of the face; but here the condition is rather one of fixation of the skin than of the muscles; the skin becomes like parchment, so that one cannot pick it up between the fingers; it feels firm or almost hard, and the patient becomes unable to open the mouth properly because the skin will not bend in the right way. The disease is of slow onset and gradual progress, so that there is seldom difficulty in diagnosis, but occasionally there are acute exacerbations in the sclerodermia process, with rapid increase in the local pain and stiffness, and then there may be difficulty in distinguishing it at the moment from true trismus. The same remarks apply to a still rarer state of things in which the sclerosing process is not confined to the skin, but affects, in varying degrees, the muscles, mucous membranes, and nerves as well, producing stiffness and pain, the nature of which may escape recognition until the patient has been watched for days or weeks in anxiety. Trichinosis may be simulated by these cases of subacute or acute *dermato-myositis*, *mucro-dermato-myositis*, or *neuro-mucro-dermato-myositis* (Fig. 559, p. 702), which are fortunately uncommon. As a rule the infective processes in the skin, muscles, and mucous surfaces in these cases are not confined to the face; there will generally be painful muscles and stiffening skin-patches on the trunk or on the limbs as well, to assist in the diagnosis. Herbert French.

TUMOURS.—(See also SWELLINGS, pp. 804 to 856.)

TUMOURS OF THE SKIN.—(See also NODULES, p. 500.)

Malignant Tumours which affect the skin include *carcinoma*, *epithelioma*, *Paget's disease*, *sarcoma*, *mycosis fungoides*, and *xeroderma pigmentosum*.

As a rule *cancer en cuirasse* (Fig. 664) and *nodular* (lenticular) *cancer* are secondary to cancer of the breast or other parts, and their diagnosis is self-evident. In *melanotic carcinoma* the tumours differ greatly in size, and also in colour, varying from a slate tint to bluish-black; they appear more frequently on the genitalia and the extremities than elsewhere. The only condition from which melanotic cancer requires to be distinguished is *pigmented sarcoma*, and for this histological examination is necessary. Either may result from a relatively small primary growth, for instance in the retina of one eye, or in a pigmented mole; the eye may have been removed for the primary growth many even ten or twenty years previously.

Epithelioma begins usually as a single growth, superficial, deep-seated, or papillary; but all the forms alike are marked by peripheral extension, infiltration and destruction of neighbouring parts, central ulceration, and (except in rodent ulcer, for which see ULCERATION OF THE FACE, p. 892) a tendency to the formation of secondary growths in lymphatic glands or in viscera. Epitheliomata have a predilection for the natural orifices, or such moist parts as the glans penis, for exposed regions, and parts exposed to friction and trivial injuries. A wart, a mole, an ulcer, lupus vulgaris lesions, or an X-ray cicatrix, may be the starting-point. If the tumour begins in the skin it appears first as a papule; if in a gland, as a nodule. In the former, the more frequent case, the papule becomes firmer and extends laterally; infiltration is evidenced by the hard, raised, pearly border. Ulceration occurs in the centre of the growth while extension is proceeding in the depths and at the sides. If the necrotic process involves the vascular tissue, there is more or less hæmorrhage. If the lateral extension predominates, the discoid type of epithelioma, as in sweep's cancer of the scrotum, is the result; the surface is raised, with a steep border, and is bright-red, with a firm, granular surface. If the granulations are of large size, the growth is of the papillary type. The chief diagnostic features of epithelioma are: the origin as usually a single growth, the site, the starting-point, the slight discharge, the characteristic border, the secondary growths in glands and elsewhere. From a wart or a mole epithelioma in its early stages can be distinguished conclusively only by microscopical examination; should ulceration or crustation appear, epithelioma should be suspected. The so-called tubercular ulcerating syphilides are, as a rule, multiple, and not rounded, but rather segmental. (For the diagnosis of epithelioma from lupus vulgaris, see under NODULES, p. 500.)

Paget's disease, occurring chiefly in women after the age of forty, begins as a reddening of a patch of skin, usually on or around the nipple, followed by branny desquamation. Infiltration soon produces a bright-red, granular, indurated surface, with a sticky, yellowish discharge, which by forming crusts may obscure the nature of the lesions, save at the border, which continues to be characteristic—sharply defined, indurated, and sometimes distinctly raised. After a period, which is usually about two years but may be much longer, deep-seated parts may become affected, this extension of the disease showing itself

Fig. 661. Cancer in carcinoma.

on the breast by retraction and induration of the nipple and the formation of a tumour in the substance of the gland. In the early stage Paget's disease has to be distinguished from *chronic eczema*, which it resembles closely. Its differentiating features are the bright-red, granular surface exposed after removal of the crusts, the induration at the well-defined edge, the intractability, the age of the patient, and (later) the retraction of the nipple. The diagnosis may be made certain by microscopic examination of scrapings in iodized serum or liquor potassæ, when the bright, oval, nucleated bodies previously thought to be psorosperms will be seen, some still contained within the host-cells, others surrounded by distinct capsules.

Sarcoma of the skin is most frequently secondary to growths commencing in the lymphatic glands or the deeper structures. *Sarcomata* vary considerably in colour, from reddish to brown or bluish-black, and also in consistence: those of the spindle-celled type are fairly firm, the small-celled ones soft, with all intervening grades of density. They may appear in any part of the body, but are often found in connection with moles, warts, or ulcers. The diagnosis usually depends upon histological examination, and it must suffice to say that a tumour which arises in previously healthy skin, or in a mole or wart, or at the site of an injury, which is soft and reddish from the vascularity that is a marked feature of this kind of tumour, or bluish from pigment, and which, after a period of slow growth, enlarges rapidly, projects above the surface, and readily ulcerates and bleeds, is probably a sarcoma.

In the early stage of *mycosis fungoides* the lesions are dull-red or livid patches, sometimes slightly tinged with yellow, varying in size from the area of a finger-nail to that of the palm of the hand, with border sometimes well marked, sometimes fading off, most frequently raised or thickened, but occasionally flat. At first the patches are smooth and dry, afterwards they become scaly, and later still they may be moist or covered with crusts. Presently the surface becomes infiltrated, and tumours as small as a pea or as large as an apple, firm and lobulated, broader at the free than at the attached end, and somewhat resembling tomatoes, project above the level of the skin ('*fungoides*'). As a rule, progressive thickening occurs, leading on to fungation. The lymphatic glands may be enlarged throughout the body. In the premycotic or eczematous stage which is sometimes absent the diagnosis may hesitate between *mycosis fungoides* and an eczematous or urticario-eczematous condition, and in some cases it may be impossible at this stage to distinguish definitely between the two: but in *mycosis fungoides* the lesions will make little response to therapeutic measures with the exception of X rays, the red of the patches may be slightly tinged with yellow, and they are more persistent than those of eczema. The only malignant condition which *mycosis fungoides* in the mycotic stage at all resembles is sarcoma, but there is seldom any difficulty in distinguishing between the two.

The initial lesions of *xeroderma pigmentosum* (Kaposi's disease) are small spots resembling freckles, but rather darker, which appear chiefly on the face, neck, arms, and legs, and generally begin within the first two years of life. Usually they disappear in winter and return in summer: but after a time they become permanent, and often quite black. At first, the condition suggests nothing but excessive freckling, but presently amid the 'freckles' appear white, glazed, atrophic spots, telangiectases, and superficial ulcers discharging pus which dries into yellow crusts. After some years, small, warty-looking growths develop on the 'freckles'. Tumours now form and ulcerate, producing fungous masses, and the process extends both widely and deeply, and destroys every tissue it encounters, not excepting bone. It is only in the earliest stage that there can be any difficulty in recognizing this very distinctive disease. In that stage it may be mistaken, as is suggested above, for simple lentigo, from which there may be nothing but the more extensive distribution to distinguish it. With the appearance of the later lesions lentigo will be dismissed from consideration, and it should be not less easy to rule out sclerodermia.

Benign Tumours of which the diagnosis may be, in very different degrees, open to doubt, are *sebaceous* and *dermoid cysts*, *fibroma molluscum*, *neurofibromata*, *myoma cutis*, *myxoma*, the *xanthomas*, *rhinoscleroma*, *molluscum contagiosum*, *colloid milium*, *benign adenoides cysticum*, and *keratosis follicularis*.

Sebaceous cysts, seen most frequently on the scalp, the face, and the back, rounded, often somewhat flattened on the top, and sometimes as large as an orange, are distinguished from *fatty tumours* by the absence of lobulation and the fact that the sebaceous contents can be squeezed out when there is an opening: in *Dercum's disease* (p. 509) the deposits of subcutaneous fat may be less well defined, but the diagnosis is generally obvious from the alcoholic history. *Dermoid cysts* may resemble *fibromata*, but if they are incised a sebaceous-looking material escapes. *Fibroma molluscum*, a pear-shaped or rounded fibrous tumour, usually covered by smooth skin and pedunculated, varying in size from a pin's head to an orange, and nearly always multiple (*Fig. 657*, p. 866), differs from a sebaceous cyst by its solid structure, and from a fatty tumour by its usual pedunculation and the

absence of lobulation. *Neurofibromatosis* or *von Recklinghausen's disease*, of which the lesions consist of nodular tumours, sometimes associated with patches of coffee-coloured pigmentation, is differentiated from ordinary fibroma in that the tumours are composed of fibrous and nervous, and not simply of fibrous, tissue. There is also a perceptible thickening of the nerves of the arms. The tumours, which have their origin in the sheaths of the nerve-fibres, and range in size from a pin's head to very large dimensions, are sometimes mistaken for rheumatic nodules, but instead of specially affecting the region of the elbows and the scalp, they occur on the trunk and extremities generally, nor is there (except from coincidence) a history of rheumatism.

Superficial *myoma cutis* occurs in the form of nodular tumours on the arms, back, chest, and face: the deeper kind, originating in the subcutaneous muscular structures, occurs as a solitary tumour, commonly on the breasts and genitals. The former growths are soft and elastic, and, like the latter, are often painful. The distinctive clinical feature of myoma cutis generally is that it contracts under the influence of cold. This, with the pain, the absence of any tendency to ulceration, and the aspect and slow course of the growth or growths, should enable the affection to be identified.

Myxoma, when it arises in the skin—most frequently in the loose skin of the scrotum and labia—usually forms rounded, pedunculated, translucent tumours, which tend to enlarge slowly. They have to be distinguished from *molluscum contagiosum*. This begins by the formation of small growths that have been likened to tiny mother-of-pearl shirt-buttons. They are usually flattened at the top, where as a rule there is a depression in which can be seen a small aperture leading into the interior of the tumour. Through this orifice a whitish material, or sometimes a milky fluid, can be squeezed out. When they are very small the tumours resemble the vesicles of *varicella*, but a microscopic examination of the contents will obviate the confusion. A molluscum body on the genitals may resemble a hard chancre, but similar growths will be found elsewhere.

Fig. 665. *Xanthoma diabetorum*: illustrating the papules on the extensors of the elbows.

Xanthoma planum, often associated with jaundice and migraine, and characterized by the formation of yellow or yellowish-white plaques (rarely nodules), usually in the upper eyelid and sometimes affecting also the lower lid, is easy of recognition, the appearance of the yellow patches embedded in the corium, and almost imperceptible to the touch, being absolutely distinctive. *Xanthoma multiplex*, however, is not identified quite so easily. Here the lesions are nearly always nodular, and often observe a linear grouping, and the colour varies, a blackish or reddish pigment being mixed sometimes with the yellow. Usually the nodules occur in connection with hepatic disease. The condition has been confounded with *urticaria pigmentosa*, but there is no itching, there are no wheals, and it is impossible to produce factitious lesions. The tumours may be indistinguishable from multiple dermoids of the skin until microscopic examination is made. *Xanthoma diabetorum* (Fig. 665) differs from other forms of xanthoma, *inter alia*, in the presence of a raised red area around the yellow spots. This feature has led, in the early stages of the affection, to confusion with *acne*, but if the lesions are punctured they will prove to be solid. In the same stage the lesions may simulate those of *lichen planus*, but the resemblance soon disappears.

Rhinoscleroma begins, usually before the age of forty, in and around the nostrils as nodules in the cutis, and in the deeper layers of the mucous membrane. These coalesce to form a hard, smooth, glistening growth which spreads inwards from the lip, and downwards to the pharynx from the posterior nares. The growth does not break down spontaneously, but is generally slowly progressive. It is not likely to be mistaken for anything but *epithelioma*, which is prone to ulcerate, generally has infiltrated edges, seldom attacks the upper lip, and usually begins later in life. In *rhinophyma*, pustules are often present, the growth is soft, and there is vascular dilatation.

In *colloid milium*, small, yellow, cyst-like formations containing a gelatinous substance

appear in the skin, chiefly on the upper part of the face. They may become depressed in the centre and be absorbed slowly, or may inflame and dry up. The only condition from which colloid milium needs to be distinguished is *epithelioma adenoides cysticum*, in which the tumours, shining and translucent, contain one or more white, brightly refracting, milium-like bodies. The face is the part attacked most frequently, but the growths may appear on almost any part of the body. They are not yellow, like the growths in colloid milium, nor are they soft.

Keratosis follicularis (Darier's disease) begins as small brown or yellow crusts, hard and dry, which, when detached from the underlying tissue, are found to present on their under surface a softish prolongation which dips into a follicle. At first discrete, the lesions may become confluent, and there is thickening of the affected parts until nodular masses are formed from which oozes an offensive discharge. The affection is slowly progressive. At the outset the condition may be mistaken for *keratosis pilaris*, but it is not confined to the situations affected by that disease. The prolongation into a follicle gives it some resemblance to molluscum contagiosum, but it has a less limited distribution, nor have the growths the pearly appearance of the molluscum bodies, while the aperture in the individual lesions is larger.

Ernest Darier.

TYMPANITES.—(See METEORISM, p. 485.)

ULCERATION OF THE CORNEA. The course of all corneal ulcers conforms to a general type, though the clinical varieties may vary. The process begins with an infiltration in the substance of the cornea, either central or peripheral; the result of this infiltration is a local loss of transparency, though in early stages the surface of the cornea may still retain its polish. The infiltration proceeds to suppuration, which is followed by a loss of substance, the corneal surface being dull and irregular, and, in the centre of the ulcer, depressed below the surrounding level. The base of the ulcer is grey or yellowish, and the surrounding portion of the cornea may be opaque with more or less grey infiltration.

The suppuration is followed, in cases which have a favourable termination, by vascularization, superficial vessels from the surrounding conjunctiva encroaching on the cornea and invading the suppurating area. The vascularization is followed by cicatrization, the surface of the cornea again becoming polished but flattened and opaque. The opacities resulting from corneal ulcers are localized, well defined and opaque, in contrast to the diffuse indefinite haze which follows such non-suppurative forms of inflammation as interstitial keratitis. Corneal ulcers may not heal, but occasionally lead to perforation of the cornea, prolapse and adhesion of the iris, anterior polar cataract, or panophthalmitis. Iritis, iridocyclitis, and pus in the anterior chamber (hypopyon) may also be associated conditions. The usual subjective symptoms are pain, photophobia, and lachrymation. The presence of corneal ulcers is demonstrated most satisfactorily by the instillation of a drop or two of fluorescein, which stains necrotic corneal epithelium or exposed corneal substance green. The brightly-stained ulcer shows up in well-marked contrast to the surrounding clear cornea.

Corneal ulcers may occur in the following clinical varieties:

Catarrhal, or simple infective ulcers. These usually occur as minute grey infiltrated spots in the centre or periphery of the cornea. They heal rapidly as a rule. They may follow injury to the corneal epithelium by foreign bodies, or may be associated with acute conjunctivitis or rhinitis.

Phlyctenular ulcers are associated with phlyctenular conjunctivitis, the ulcer forming after the epithelium on the top of a phlyctenule has been rubbed off. They are usually marginal, but may occasionally make their way on to the cornea, a leash of conjunctival blood-vessels trailing after them. Similar ulcers may be associated with *acne rosacea*.

Hypopyon ulcer, or ulcus serpens. This is a shallow ulcer affecting chiefly the superficial layers of the cornea in or about its centre. The middle layers of the cornea are comparatively unaffected, but at the posterior surface the infiltration again becomes dense, with much fibrin and debris, associated with the formation of more or less pus in the anterior chamber (*Fig. 234*, p. 287). The ulcers often perforate; they are usually due to infection with the pneumococcus. The pus in the anterior chamber is always sterile, unless there is perforation of Descemet's membrane. These ulcers do not react to ordinary methods

of treatment as a rule, but require cauterization, either by pure carbolic acid or by the galvano-cautery. The hypopyon then disappears rapidly.

Mooren's ulcer, or *rodent ulcer of the cornea*, is a chronic ulcer, usually affecting the eyes of elderly people. It begins at the margin of the cornea and spreads slowly over the whole surface, the advancing edge being much undermined. The ulcer is always shallow, and perforation never occurs: the ulcer may heal in places, but this is seldom permanent, and the ulceration usually spreads over the whole surface of the cornea whatever method of treatment may be employed to arrest its progress, though radium has been used with some success. No specific organism has yet been discovered.

A *dendritic ulcer* is characterized by its peculiar shape—a long central stem with small linear ramifications. It is not really an ulcer, but an infiltration under the corneal epithelium, which in the later stages may become necrotic and break down. It is best treated by rubbing off the affected corneal epithelium with a pointed stick dipped in absolute alcohol.

Corneal ulcers may occur in association with pannus in *trachoma*, their usual site being at the margin of the vascular area. Occasionally they penetrate more deeply into the corneal substance.

Corneal ulcers frequently follow *gonorrhoeal* and *diphtheritic conjunctivitis*. They spread rapidly, and often lead to perforation of the cornea and panophthalmitis. The diagnosis depends on bacteriological methods and the discovery of the causative micro-organisms.

Keratomalacia, a disease of childhood, is associated with night blindness and xerosis or dryness of the conjunctiva. Characteristic foamy white patches are seen on both sides of the cornea. The cornea becomes dull, grey, and cloudy, and ultimately disintegrates from purulent infiltration, associated with very slight signs of ocular inflammation. The ocular condition is associated with marasmus and malnutrition. The prognosis, both as to eye and vision, is bad.

Keratitis e lagophthalmo is associated with paralysis of the seventh nerve. Owing to the failure of the orbicularis palpebrarum the eye cannot be closed, and does not remain closed during sleep. The lower part of the cornea is exposed, becomes dry, and the corneal epithelium dies, with consequent ulceration of the cornea. The condition can be cured by diminishing the palpebral aperture by sewing the eyelids partially or completely together.

Similar exposure of the cornea and consequent ulceration is seen occasionally in cases of EXOPHTHALMOS (p. 283), for instance in severe *Graves' disease*.

Keratitis neuroparalytica: in paralysis of the fifth nerve, or as a result of excision of the Gasserian ganglion, the cornea becomes dull and cloudy and necroses in the centre, only the periphery remaining clear. A hypopyon forms, and in some cases the whole eye is destroyed, though occasionally the keratitis may lead only to a permanent opacity. The condition is due to arrest of lachrymal secretion and absence of corneal sensation, which is followed by abolition of the winking reflex. Foreign bodies lodge on the cornea and are not removed. The prognosis is bad, and is little affected by treatment.

Corneal ulcers may be associated with *herpes frontalis*, vesicles forming on the cornea simultaneously with the vesicles on the skin, especially along the course of the supra-orbital nerve. The ulceration is often severe and may lead to perforation and destruction of the eye, and is apt in any case to be followed by considerable corneal opacity. The cornea is usually insensitive, and the intra-ocular tension may be raised.

Tuberculous ulceration is fortunately not common, but it should be borne in mind as a possibility in chronic or resistant cases. The diagnosis depends on the history, the presence of tuberculous glands or other similar lesions, positive reaction to the various tuberculin tests, and, most conclusively of all, upon the detection of tubercle bacilli in the discharge from the ulcer itself.

Herbert L. Eason.

ULCERATION OF THE FACE. The ulcers most often met with on the face are lupous, serofulous, syphilitic, or malignant. In *lupus vulgaris*, the ulceration is extremely chronic. The lesion begins as a papule, develops into a nodule, and after a while, in the majority of cases, the lupous tissue breaks down and forms a granular sore covered with greenish-black crusts: but around the ragged edge will still be seen the characteristic 'apple-jelly' nodules in different stages of development. The ulceration may extend

through the whole thickness of the skin and may become the seat of warty vegetations. In the nose, where the integument is thin, it may cause necrosis of cartilage. The course the pathological process runs, from the papule onwards, as here described, and the frequent presence of the different lesions simultaneously, shed sufficient light on the character of the ulceration. The ulcer of lupus, however deeply it may extend, never erodes bone. This alone is sufficient to differentiate lupus from the ulcers of syphilis and cancer. It nearly always begins before the age of twenty.

In the ulcers of *scrofula*, though they have no absolutely distinctive characters, it will often be noticed that the edge is undermined and the surrounding skin blue and of low vitality. Their occurrence in children of strumous aspect, or in elderly persons who bear the stigmata of scrofulous lesions dating from childhood, and their tendency to become chronic owing to the feeble resistance offered by the tissues to morbid processes, leave no room for doubt as to their true nature.

It is in the late secondary and the tertiary stages of *syphilis* that cutaneous lesions on the face, as elsewhere, are prone to ulceration, instead of to the resolution to which typical secondary syphilides tend. The whole structure of the skin, or mucous membrane, is frequently involved, the ulceration is deep, and the ulcers, while healing in the centre, are prone to extend at the margins, and so assume the characteristic circinate or serpiginous form. The appearance of the ulcers, with the history, and the marks of earlier syphilitic lesions, will supply all the guidance the diagnostician needs: Wassermann's serum test and the effects of mercury and iodide of potassium or salvarsan may serve to clinch the diagnosis.

As a rule *rodent ulcer* or basal-celled carcinoma occurs in persons of more than middle age, and its favourite points of attack are the outer edge of the orbit and the side of the nose. It begins as a small, circumscribed nodule, dull brownish-red in colour, flat, depressed in the centre, and firm to the touch. After, it may be, years, the cuticle covering it is broken, and an ulcer is formed with depressed granular centre and infiltrated border. Very slowly this extends, both in circumference and in depth, infiltrating and destroying the subjacent tissues, including bone. Usually the destruction of the underlying parts is more marked in the centre, so that the ulcer becomes crateriform. Its invariable features—the inconsiderable suffering it inflicts, the singular slowness of its progress, its depressed centre, the firm, raised, rolled edge (*Fig. 671*, p. 895), its failure to affect neighbouring glands, and its incurability except by extirpation or by physiotherapy—are so characteristic as to leave little scope for alternative diagnosis. It differs from *squamous epithelioma* in that the latter is more exuberant in its growth, has a very hard and everted edge, and a foul base roughened with granulation, is often attended by severe pain, is much more rapid in its course, and affects the glands in its vicinity. It differs from *lupus vulgaris* in its mode of onset, in the absence of the 'apple-jelly' nodules, and in not being a disease that starts in childhood. It may be diagnosed from tertiary syphilitic ulcers by the characters described above, and also by its usually solitary character and its resistance to treatment.

Leptous ulceration of the face will be suggested by geographical considerations, and distinguished from syphilis, tubercle, rodent ulcer, or epithelioma by microscopical examination; particularly by demonstration of leprous bacilli in parts excised and examined histologically.

Actinomyotic ulceration is seldom confined to the skin alone: the process starts in the deeper structures and affects the skin later: infiltrating it, reddening it, and leading to multiple chronic sinuses, especially over the jaw or down the neck. Syphilis, tubercle, or epithelioma may be simulated, but the diagnosis is decided when the typical ray fungi are found microscopically in the discharge (*Fig. 619*, p. 779). *Ernest Dore.*

ULCERATION OF THE FOOT. The ulcer which attacks the foot specially, though not exclusively, for the hand may be affected in the same way, is that known as *perforating ulcer* (*Fig. 666*). The exciting cause is pressure upon or injury to a foot in which there is interference with the nerve-supply, either from peripheral lesion, as in peripheral neuritis, or from damage to the nerve-trunk, as in leprosy, syphilis, or diabetes mellitus, or to the nerve-centre, as in *tubes dorsalis*, general paralysis, or syringomyelia. The commonest situation of the ulcer is at the point of greatest pressure—the under aspect of the metatarsophalangeal joint of the big or little toe. The ulcer, which is more a

sinus than a true ulcer, usually painless, may be simple or multiple, and both feet may be affected. It often begins by suppuration under a corn. When the horny covering is cast off, a track is seen which extends downwards until the bone is exposed. The process is usually very slow, and if the pressure from walking is continued the thickened epidermis forms a kind of corn-shield around the opening. The more essential symptoms of the disorder of which perforating ulcer is but an incidental manifestation will disclose the true nature of the lesion. The only malady with which it can be confused is a suppurating corn. From this it is distinguished by the absence or small degree of pain, and by its irresponsiveness to the simple surgical treatment to which a suppurating corn yields readily.

Ulceration of the foot is also apt to arise as the result of rubbing, irritation, or other injury to parts whose nutrition is impaired, for example in cases of talipes from nerve disorders or when sensation is impaired, as in cases of syringomyelia, or paraplegia.

Mycetoma is a fungous disease that is known alternatively as Madura foot, because, endemic in Madura and other parts of India, it usually affects the foot or the leg, though sometimes the hand, and in rare cases the shoulders or the scrotum. The affection appears in several forms, according as they are due to different species of *Discomyces* and *Aspergillus*. The lesions may be black ('melanoid') or pink ('ochroid'). The disease begins with slight swelling and redness or local induration, and as it progresses the foot swells and the surface becomes dotted with small nodules, each containing the opening of a sinus which discharges a viscid, syrupy, slightly purulent, sometimes blood-streaked fluid, in which are suspended rounded greyish, yellowish, or black granules. As the foot enlarges, the leg, from disuse, atrophies. The only condition from which mycetoma needs to be discriminated is *actinomyces*. This affection usually begins in the bone or other deep structures of the jaw, face, or neck, may thence spread to the surface, and may involve the viscera. In the discharge the ray fungus may be found in the form of tiny, friable, yellowish or greyish bodies, though microscopical methods and the discovery of the characteristic ray fungi (*Fig.* 610, p. 779) will generally be required before the nature of the case can be confirmed.

Fig. 666 Perforating ulcer of the foot from a case of *tuberculous*.

Ulcerations of the foot resulting from *frostbite*, excessive *chilblains*, *burns*, or *injury* are generally self-evident: similar changes due to vascular spasm (*Raynaud's disease*: *intermittent claudication*), or actual arterial occlusion by *atheroma*, *thrombosis*, or *embolism*, need to be diagnosed from the collateral evidence of vascular derangements. *Ernest Dore*.

ULCERATION OF THE LEG may be classified under three headings: (1) *Non-infective ulcers*: these include those that are not due to any specific infection, but which are caused by various factors which interfere with the vitality of the part by injury, lack of circulation, or deficient innervation of the tissue. (2) *Infective ulcers* resulting from the direct action of a definite specific infection, e.g., *tuberculosis* or *syphilis*. (3) *Ulcerating tumours*: these are malignant tumours, which have originated in or invaded the skin.

Non-infective Ulcers: Varieties and Causes.

Varicose Ulcer. The presence of varicosity in the veins of the leg diminishes the free return of blood and so leads to congestion and interference with nutrition, and thus to ulceration. In most cases the ulcer is on the inner side of the leg about three inches above the ankle. It may be small, or may encircle the limb. For some distance round the ulcer the skin suffers from the effects of passive congestion: it becomes indurated and of a purplish-brown colour, and numerous small varicose veins or telangiectases may be seen

in it. Any slight injury may cause abrasion of this weakened skin and thus another ulcer. The presence of varicose veins associated with an ulcer will usually lead to the conclusion that the latter is dependent on the former, and that view will probably be correct, but it may not be the whole truth, for syphilitic and varicose ulcerations may be present at the same time. Wassermann's test for syphilis should be carried out in all cases.

Lymphatic Obstruction also leads to loss of nutrition, and ulceration may result. The best instance is seen in elephantiasis due to *Filaria sanguinis hominis*. In this country elephantiasis is rare. Other instances that may be cited are swellings of the leg following a badly united fracture: the cicatricial contractions of extensive burns: phlegmasia alba dolens, or white leg, during pregnancy or after labour.

Atheroma of the Arteries leads to a feeble or imperfect circulation of the blood, and so to loss of nutrition. Ulcerative conditions of the lower part of the leg are common in such cases, and even gangrene may result.

Old Age.—Owing to a weaker condition of the tissues, ulcers are much more frequent in old people than in the young.

Cold.—A similar condition is brought about by exposure to cold, especially in persons whose nutrition is imperfect, whether from bad or insufficient food. The first effect of cold is to produce a chilblain: this if rubbed or irritated may degenerate into an ulcer.

Trauma.—In a normal individual, any lesion of the skin of the leg, such as that caused by a kick, a scratch, or a cut, will heal quickly, and no ulcer result. Circumstances may arise which interfere with the healing process. Perhaps the most frequent cause which leads to the formation of an ulcer is infection with pyogenic organisms, and the prevention of the discharge from the wound. Occasionally there is also accidental contamination of the wound with some specific organism, such as that of diphtheria or phagedæna.

An important cause of want of healing of an ulcer is interference with its contraction. If contraction is impossible, as when a sore is situated over and adherent to a bone, healing may come to a standstill.

Deficient Innervation leads to loss of nutrition. Examples are seen in infantile palsy: rubbing of the

foot or pressure of an instrument is prone to be followed by an obstinate ulcer. In cases of hemiplegia, even when the patient is lying on a water-bed, ulceration in the form of bed-sores will occur much more rapidly on the paralysed side than on the other. Perforating ulcer of the foot (p. 892) is a well-known sequel of *tuberculous*; its other common cause is *diabetes mellitus*—

ulceration and GANGRENE (p. 317) are prone to occur because the resistance of a diabetic individual to micro-organisms is lowered, also because the arteries are often atheromatous, and possibly because the innervation of the whole body is interfered with.

Varicose or syphilitic ulceration of the leg may be simulated by a *maligner* who wishes to escape conscription or for some other reason desires to make out that he is ill: nitric acid or other corrosive may have been rubbed into the leg, and the diagnosis may be obscure unless the circumstances of the case are known well. Sometimes the diagnosis is suggested by the rectangular or other definite shape of the ulcer itself (Fig. 667).

Infective Ulcers. The legs may be attacked by any form of acute infective ulcer,

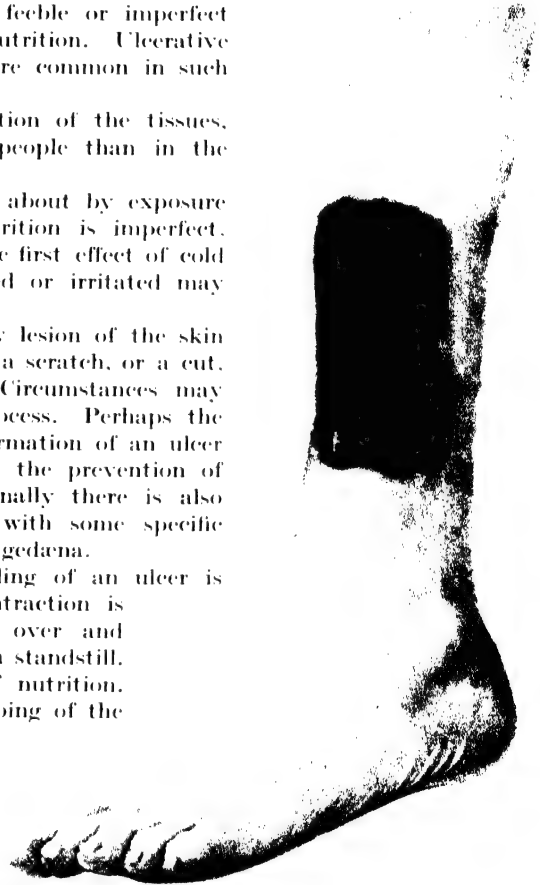

Fig. 667. Ulceration of the leg in a maligner. The more or less regular shape of the ulcer is suggestive of an artefact: it was admittedly done with nitric acid.

such as *anthrax* or *glanders*, but such an event is rare. The chief ulcers that belong to this group are chronic, and due to syphilis or tuberculosis.

Syphilitic Ulcers are the result of gummata which have formed in the subcutaneous tissues. These ulcerated gummata are almost always circular, and present a punched-out appearance (*Fig. 668*): they are generally multiple and tend to run into each other, so that the ulcer has a serpiginous outline. They tend to heal at one side while they progress at another. The scars are thin and supple, and if in the lower part of the leg, usually pigmented round the edges, white and slightly depressed in the centre. Gummata are often found with varicose veins or ulcers, and it seems probable that the low state of nutrition of the tissues caused by the obstruction of venous return is favourable to their formation. Diagnosis can in most cases be made on the distribution and shape of the ulcer, especially if it is on the outer aspect of the lower third of the leg; on the presence of other signs of syphilis; and on the effect of giving iodide of potassium or salvarsan; or by finding a positive Wassermann's reaction.

Tuberculous Ulcers usually follow the formation and bursting of tuberculous abscesses, starting either in the subcutaneous tissue or in a bone, and the history may help materially in diagnosis. The ulcer is very chronic, and is characterized by undermining of the skin for a considerable distance from the edge (*Fig. 669*). The surface is pale, the granulations are small, with here and there small areas of caseation. Primary tuberculosis of the skin, or lupus, is not often found on the leg, though it may occur there as in any other part of the skin. A useful guiding rule is that lupus never starts later than the age of twenty and lasts for years, whereas a gumma starts at a later period and tends to heal spontaneously. In lupus the chief characteristic is the presence of minute, semi-transparent nodules at the margin of the ulcer and in the skin around resembling apple jelly. If further methods of diagnosis are required, a diagnostic injection of Koch's old tuberculin may be used, or von Pirquet's skin test applied. A particular variety of tuberculous ulcer of the legs is described on p. 502 under the heading of Bazin's disease, or erythema induratum serofulosorum.

Ulcerating Tumours. *Epithelioma* may develop in a simple varicose ulcer that has existed for many years. The change may be very slow, or rapid. The ulcer spreads, the edges become heaped-up, everted, and indurated (*Fig. 670*). The femoral lymphatic glands become enlarged, and if the disease is allowed to progress, the bone is attacked. If any doubt arises as to a change in the character of an ulcer, a piece from the edge should be removed for histological examination.

Rodent Ulcer (*Fig. 671*) usually attacks the face, though it may be found on any part of the body.

Sarcoma, starting in the deeper tissues, may fungate through the skin and give rise to an irregular breaking-down mass, which is obviously malignant, but may be mistaken for epithelioma unless there is previous knowledge of a malignant bony tumour or unless histological examination is resorted to.

George E. Gask.

ULCERATION OF THE THROAT. (See SORE THROAT, p. 757.)

ULCERATION OF THE TONGUE. To enable a good view to be obtained of the affected part the patient should be seated in a strong light and the protruded tongue gently wiped with a piece of soft linen to remove moisture. The presence of an ulcer being ascertained, its nature may be considered under the following heads: (1) *Carcinomatous*;

Fig. 668. Diagram of a gummatus ulcer. Clearly punched out. Slough on base.

Fig. 669. Diagram of a tuberculous ulcer. Undermined edges.

Fig. 670.—Diagram of an epitheliomatous ulcer. Growth in excess of destruction. A, Normal skin; B, Heaped-up edges; C, Ulcerated portion.

Fig. 671. Diagram of a rodent ulcer. A, Normal skin; B, Smooth, wire-like edges; C, Shallow cavity. (From Professor Rutherford Morrison's 'Introduction to Surgery'.)

(2) *Syphilitic* ; (3) *Dental* ; (4) *Tuberculous* ; (5) *Dyspeptic* ; (6) *Ulcer in connection with stomatitis*.

1. **Carcinomatous Ulcer** is much commoner in men than in women. It is practically unknown before the age of thirty, and rarely starts before forty-five. The ill and wearied expression of the patient may awaken suspicion before the tongue is seen, for the pain

Fig. 672. Epithelioma of the tongue in a stage preceding ulceration.

Fig. 673. Epitheliomatous ulceration of the tongue.

Fig. 674. Quite early epitheliomatous nodule developing upon a leucoplakic syphilitic tongue.

Fig. 675. A nodular mass in a leucoplakic syphilitic tongue of a type in which it is not possible to say whether malignant changes have begun without histological examination. In this case there was no malignancy, but in another with almost identical appearance, there might be.

and trouble caused by an epithelioma have a rapid and marked effect. The tongue in a normal individual can be protruded from one to one and a half inches beyond the teeth ; if the protrusion is limited, or if the tongue is not protruded straight, it can generally be inferred (except in cases of paralysis) that there is some tumour binding it down. The position of the ulcer is to be studied and its relation to any sharp and carious tooth. Usually an epithelioma is on the side of the tongue, but there is no rule ; it may be anywhere on the upper, lateral, or under surface, or on the floor of the mouth.

As regards the ulcer itself, the typical appearance, when fairly developed, may be described as irregular, deep, foul, sloughy, with raised nodular everted edges, and a surrounding area of induration. The lymphatic glands are enlarged and hard, and they may be fixed. The submaxillary set is generally the first affected, but the disease sometimes misses these and infects the carotid and even the supraclavicular glands. Examination, therefore, should not be concluded before the whole of the neck has been palpated. The diagnosis should have been made, however, before the disease has developed thus far: in its earliest stages an epithelioma may be represented by a superficial ulcer no more than a sixteenth of an inch in diameter, by a crack or a small lump, without any enlargement of the glands. In all these conditions, however, the ulcer is already hard and very resistant to any form of treatment. Any ulcer of the tongue occurring in a middle-aged man, and lasting for more than two or three weeks, should awaken suspicion. (*Figs. 672, 673.*)

Diagnosis from Syphilitic Ulcer. This may be a very real difficulty, owing to the fact that the two conditions may exist side by side, and that the syphilitic leucoplakia or leucomic wart may be the actual precursor of a cancer. A positive Wassermann's reaction, therefore, is not proof that an epithelioma is not present. If a well-formed gumma is

Fig. 676. Tertiary syphilitic (gummatous) ulcers of the tongue.

Fig. 677. Tuberculous ulcer of the tongue.

present, antisiphilitic remedies soon make a great change in its appearance, and a diagnosis may be made in this way, but not more than ten or fourteen days should be allowed to pass in uncertainty. There are many cases in which the cleverest surgeon is in doubt, and seeing the rapid course this disease runs, and the vital importance of securing an early diagnosis, it is urged with great insistence that the only certain method, and the one to be employed early, is that of taking out a piece of the ulcer, or, if small, the whole ulcer, and submitting it to histological examination. (*Figs. 674, 675.*)

Diagnosis from Dental Ulcer. The ulcer in this case is caused by a bad tooth, and therefore is in a position on the tongue corresponding to the latter. Further, the ulcer is soft to the touch, and heals rapidly when the offending tooth is stopped or extracted. There is seldom difficulty in differentiation except when the ulcer is of very long standing.

2. Syphilitic Ulcer. This may be primary, secondary, or tertiary. *Primary syphilis* or *chancre* is certainly rare on the tongue, and, owing partly to its rarity and partly to the fact that it is unexpected, it is frequently missed. It is more common in men than in women, but it may occur even in children. It starts as a small pimple which ulcerates and becomes indurated, though the induration is not so marked as when it is situate on the glans penis. The appearance of a secondary rash with general enlargement of the lymphatic glands would indicate the diagnosis with certainty, which might be confirmed

by Wassermann's serum reaction, and the detection of spirochaeta in serum from the sore. Furthermore the sore heals rapidly under the influence of salvarsan.

Secondary Syphilis manifests itself by the formation of mucous patches and superficial ulcers. The latter are almost always multiple, and situated along the edges and tip of the tongue, and with them are also found similar sores on the mucous membrane of the cheek, lips, palate, and tonsil, and at the edges of the mouth. The ulcers are small, round, painful, with sharply cut edges and a greyish floor. Other secondary symptoms will be present to make the diagnosis clear.

Tertiary Syphilis or *Gummatous Ulcerations*. These are divided into superficial and deep. *Superficial* gummata begin as small round-celled infiltrations in the mucous and submucous tissue. The ulcers are usually shallow, often irregular and associated with chronic glossitis, fissures, and leucoplakia. They are extremely important, for such a condition is often followed by epithelioma. They are also very resistant to antisymphilitic remedies other than salvarsan. The ulcers themselves are not at first indurated, but if surrounded by interstitial fibrosis may appear hard: a histological examination is very desirable if there is the least doubt. A *deep* gumma starts as a hard swelling in the substance of the tongue; later it softens, breaks down, and shows itself, generally in the middle line, as a deep cavity with irregular, soft, undermined walls, and a wash-leather-like slough at its base (*Fig. 676*). It is not painful, and does not increase progressively in size. The important thing is to distinguish it from epithelioma and tuberculous disease. Unlike epithelioma, it is not hard, and its history is short. Furthermore, it yields very rapidly to potassium iodide or salvarsan.

3. **Dental Ulcer** is due to repeated small injuries from the sharp edge of a decayed tooth. It is therefore situated in such a position, generally on the side of the tongue, that it is opposite the tooth. The ulcer is single, small, superficial, and not indurated unless it is of long standing. It is therefore not easily mistaken for any other kind of ulcer, or if doubt arises it is allayed by the healing of the ulcer on stopping or extracting the tooth.

There is a form of dental ulcer which is found on the frenum of the tongue in children suffering from whooping-cough: during the violent expiratory spasms peculiar to the illness, the under surface of the tongue may suffer from rubbing over the lower incisor teeth.

4. **Tuberculous Ulcer of the Tongue** is rare, but it occurs at that period of life during which tuberculous disease of the lung is common, that is to say, between the ages of fifteen and thirty-five. It is due to infection with tubercle bacilli brought up into the mouth, and if a patient is found to be suffering from tuberculous disease of the lungs or larynx and also from an ulceration of the tongue there is a strong probability that the latter is of the same nature as the former. The ulcer itself may be situated on the tip or side of the tongue; it has an irregular outline, and the base is nodular, sloughy, or caseous (*Fig. 677*). It has often been mistaken for epithelioma or gumma. The fact that it is not hard, and that phthisis is present, should put one on one's guard. As against gumma, a Wassermann's reaction would be negative: moreover, the ulcers are often small and multiple, more nearly resembling dyspeptic ulcers, though they may be single, of fair size, with raised edges, indolent base, and chronic course. A von Pirquet's test or a diagnostic injection of Koch's old tuberculin might be employed, but a more reliable method is the removal and microscopical examination of a piece of the ulcer, when the histological appearances of tubercle will be seen. The tubercle bacillus (*Fig. 607*, p. 779) is not always found.

5. **Dyspeptic Ulcer**, as the name applies, is connected with disorders of digestion. The ulceration is often multiple, each ulcer being round, small, often covered with a greyish slough, and with a bright ring of inflammation round it. They are situated on the dorsum and edges of the tongue near the tip. There may be similar ulcers on the gums or on the inner aspects of the lips and cheeks, and the cervical glands may be enlarged.

6. **Ulcers in connection with Stomatitis (Ulcerative Stomatitis)**. Septic infection of the mouth due to a variety of causes, such as irritation from decayed teeth, alkalis, acids, or mercury, may be accompanied by the formation of small vesicles which, on bursting, give rise to superficial ulcers. They are not limited to the tongue, but appear on the mucous membrane of the cheeks and gums as well. Aphthous stomatitis commonly occurs in conjunction with the febrile diseases of childhood. It is characterized by the

formation of whitish spots on the buccal mucous membrane, and by the shedding of epithelium small superficial ulcers may be formed. The ulcers of the tongue are here, so to speak, accidental, occurring in the course of a general inflammation of the mouth, and will hardly be confounded with any other form of ulcer except so-called dyspeptic ulcers, and there is no real line of demarcation between the latter and the stomatitic variety. One type that may be resistant to treatment is produced by Vincent's angina organisms: bacteriological tests give the diagnosis, but it may be suggested by the extreme factor of the breath.

URATE DEPOSIT IN THE URINE. A precipitate of urates is often recognizable at once by its pink colour, due to their carrying down with them the uroerythrin pigment of the urine. Urates themselves are white, however, and if, as is sometimes the case, there is no uroerythrin present for them to carry down they form a white precipitate which may be mistaken for mucus, phosphates, oxalates, or pus. They may be distinguished at once, however, by warming the urine back to body temperature: they re-dissolve long before boiling-point is reached. They are also soluble in liquor potassæ, unlike phosphates. Microscopically they are nearly always amorphous, though in rare cases

Fig. 678.—Spherules and 'thorn-apple' crystals of ammonium urate.

Fig. 679.—Striated spherules and brown dumb-bells of sodium urate.

they assume the form of small spheres with irregular projecting spicules—the so-called 'thorn-apple' or 'hedgehog' crystals of ammonium urate (*Fig. 678*)—when the urine has become alkaline; or analogous striated brown spherules or dumb-bells of sodium urate (*Fig. 679*) in an acid urine.

Their only significance from a clinical point of view is that they indicate a concentrated urine. It does not follow that a urine is not concentrated if no precipitate of urates occurs, but the fact that the urates re-dissolve on warming serves to show that, although there may be enough water to keep them in solution at body temperature, the urine becomes supersaturated with them as it cools, and precipitates them out. The reason for the urinary concentration has to be learned from collateral evidence. It may be that there has been much sweating, and in hot weather a precipitation of pink urates is a very common physiological condition, which is apt to alarm some patients when they first notice it. On the other hand, the concentration may be due to pathological conditions, of which the

commonest are fevers, chronic valvular disease with heart failure, and maladies which lead to loss of fluid by vomiting, sweating, or diarrhoea. The urates themselves afford hardly any clue to the cause of the concentration, and their appearance is just the same whether their deposition is due to physiological or pathological changes.

The most marked examples of uratic deposits are to be seen in cases of acute rheumatic fever, lobar pneumonia, and chronic heart disease with failing compensation. It is a general rule, moreover, that when the kidneys are themselves affected there is decidedly less tendency for uratic deposits to form than when the primary disease is in the heart or lungs; thus when one may be in doubt as to whether a given case of chronic heart failure is due to primary renal disease or primary heart disease an abundant urate deposit affords some evidence in favour of the latter and against the former. It is no absolute rule, however, and almost any concentrated urine may precipitate urates.

Students are a little apt to confuse the significance of urates with that of uric acid, though the two are entirely independent from a clinical standpoint. *Herbert French.*

URETHRA, DISCHARGE FROM. (See DISCHARGE, URETHRAL, p. 227.)

URETHRA, FÆCES PASSED BY. (See FECES PASSED PER URETHRAM, p. 296.)

URIC ACID DEPOSIT IN THE URINE.—The most typical form taken by a precipitate of uric acid in a urine is the cayenne-pepper deposit, seldom voluminous, of characteristic light-brown, prismatic crystals (*Fig. 680*), arranged either as separate 'whetstones', or in overlapping bundles, or 'rosettes'; occasionally crystallization is imperfect

Fig. 680. Uric acid crystals.

and they appear as 'dumb-bells'. Intrinsically, they are colourless; but they differ from all other urinary deposits in that they carry down with them the ordinary yellowish-brown urochrome pigment of the urine. For clinical purposes the best test for them is the microscope.

Besides the cayenne-pepper deposit uric acid crystals may be present in considerable numbers in the midst of other precipitates, such as mucus, or oxalate of lime; in which case they may not be discernible without the use of the microscope; or, again, they may become aggregated together into small pellets or calculi, which the patient may be conscious of as 'gravel' on micturition.

A deposit of uric acid is generally found in a decidedly acid urine of high specific gravity ; but it may occur in urines of almost any reaction or specific gravity. A great deal more importance than it deserves has been attached to the supposed relationship between this uric acid and gout. A cayenne-pepper deposit by no means indicates gout ; indeed, it may be perfectly physiological, occurring abundantly sometimes in healthy young persons, particularly boys. It does not even follow from its occurrence that there is excess of uric acid, either in the urine or in the tissues ; for the precipitation depends nearly as much upon the relative proportions of phosphates, chlorides, and inorganic sulphates to uric acid, and upon the absolute and relative amounts of sodium, potassium, and other bases in the urine, as upon the absolute amount of uric acid. The greater the tendency of the bases to form phosphates, by mass action or otherwise (see PHOSPHATURIA, p. 636), the less the tendency for the soluble quadriurates, and the greater the liability for less soluble biurates, to be produced, the relatively insoluble uric acid being liberated from the latter and deposited in crystalline form.

Considerable care has to be exercised, therefore, before any useful clinical deductions can be drawn from the fact that a urine contains a deposit of uric acid. It is true that a persistent tendency to it is often associated with gout ; but the latter should be diagnosed from the collateral evidence rather than from the uric acid crystals in the urine. Many gouty subjects precipitate no uric acid in their urine at all. Naturally there will be a greater tendency to such deposition when the total amount of uric acid present is greater than normal. Uric acid in the urine is derived from two sources : exogenous and endogenous. The exogenous are such foodstuffs as are rich in nucleo-protein, and in the so-called xanthin bases, or purin or alloxuric bodies—xanthin, guanin, hypoxanthin, adenin, heteroxanthin, paraxanthin, episarkin, epiguanin, methylxanthin, and carnin—which are mainly derived from nuclein. Analyses of the various foodstuffs as to purin bases need not be given here, for it is easy to remember that broadly speaking these substances are contained in largest quantities in the richest food. A considerable proportion of the xanthin bases are excreted as uric acid, and it is common knowledge that rich foods tend to increase uric acid in the urine. Endogenous uric acid, on the other hand, is derived from the patient's own tissue metabolism. Birds excrete nearly all their nitrogenous waste as uric acid ; man excretes his mainly as urea, and only to a minor extent as uric acid. Sometimes, however, too much of his nitrogenous metabolism stops short at the stage of uric acid, instead of the latter being converted into urea ; he then excretes an abnormal total quantity of uric acid, with the result that it may be precipitated in crystalline form. One repeats, that this does not necessarily constitute gout, however ; it occurs in certain healthy subjects, in leukemia, in pernicious anemia, during the course of certain fevers, and in some cases of chronic heart disease. Perhaps one of the best ways of avoiding too narrow a conception in regard to this uric acid is to remember that in some respects the human body is a fire ; fires may burn their coal well or badly ; if well, the residue is but a little ash ; if badly, the residue is not ash, but clinker : uric acid is the clinker of the human body, and many different things that make human nitrogenous metabolism incomplete may cause a deposition of this clinker in the urine. Gout is one such thing ; but excessive eating, deficiency of exercise, biliousness, and various chronic imperfections of the circulation or digestion may do so ; and the same may occur in apparently healthy subjects who have never had any untoward symptoms at all. Oxalate of lime (see OXALURIA, p. 523) is possibly derived in part from similar imperfect combustion of carbohydrates or fats, and it is noteworthy how often crystals of uric acid and of oxalate of lime occur either together, or alternating with one another. Still further, error of metabolism may produce glycosuria in association with uric acid crystals, so-called gouty glycosuria.

Besides being evidence of overloading, or of imperfect combustion in a general sense, the occurrence of a uric-acid deposit may be of particular clinical importance in certain cases of *frequency of micturition*, of *urethritis*, and of *renal calculus*. Necessity to micturate frequently, only small quantities of urine being passed at a time, is a symptom that in young people suggests coli-bacilluria, pyelitis, cystitis, possibly tuberculous trouble in kidney or bladder ; enlargement of the prostate in men over sixty ; or some uterine or other pelvic malady in women. It is important to remember, however, that undue acidity of the urine, with a tendency to deposit crystals of uric acid, or oxalate of lime, may

produce the same symptom in considerable degree. It is sometimes spoken of as irritability of the bladder; the highly acid urine irritates the vesical mucosa, and it may produce actual cystitis. The same irritation may inflame the urethral mucosa and produce a 'gouty' urethritis; and, perhaps, epididymo-orchitis, which may be mistaken for the gonococcal form, unless pus films can be shown to contain no gonococci.

If the patient has suffered from renal colic, hæmaturia, or vesical pain, suggestive of calculus in the kidney, ureter, or bladder, the discovery of abundant uric acid crystals in the urine affords confirmation of the diagnosis of a uric-acid stone, particularly if they are obviously aggregated together into tiny calculi: there are generally red corpuscles, excess of leucocytes, and tailed epithelial cells from the renal pelvis, or pyriform cells from the deeper layers of the bladder mucosa, at the same time.

The danger of diagnosing glycosuria in the absence of sugar when uric acid is abundant in a urine needs special mention. Uric acid has considerable power of reducing Fehling's solution. It seldom gives the copious brick-red or orange-yellow precipitate that is characteristic of abundance of sugar, but it may give just enough reduction or change of colour to make it doubtful whether sugar is present or not. More than a few proposers for life insurance have suffered unfairly on this account: no such partial reduction should be regarded as due to sugar until the presence of glucose has been confirmed by other means, particularly the phenylhydrazine and the fermentation tests. *Herbert French.*

URIDROSIS. (See SWEATING, ABNORMALITIES OF, p. 803.)

URINE, ABNORMAL COLORATION OF. This may be due to: (1) The presence in abnormally large quantities of certain normal urinary pigments, such as uroerythrin; (2) The presence of pigments which are formed normally in the organism, but which are not normally excreted in the urine, such as hæmoglobin and the pigments of the bile; (3) The presence of pigments formed in the organism only under special or abnormal conditions, such as alcapton, melanin, porphyrins; (4) The presence of pigmentary substances derived from drugs or foods, or administered directly by the mouth.

Urine of unusual tints may be classified conveniently according to the colours which they exhibit, as follows: (1) *Yellow and orange urines*; (2) *Pink and red urines*; (3) *Brown and black urines, including such as are of normal tint when passed but darken on exposure to air*; (4) *Green and blue urines*.

1. Yellow and Orange-coloured Urines. The normal yellow tint of urine is wholly due to *urochrome*, for other urinary pigments are present in traces so minute that their presence has no obvious effect. However much it be diluted, normal urine remains yellow as long as any tint is visible. In some cases of diabetes insipidus the urine is almost colourless, and the abundant urine of diabetes mellitus usually exhibits a peculiar pale, bright, greenish-yellow tint.

Urobilin, when present in large amount, imparts a rich orange-yellow colour: and when seen in very thin layers, as near the apex of a conical glass, urines rich in urobilin have a pinkish tint, due to selective absorption in the middle of the spectrum. Such urines, when examined with the spectroscope, show a dark absorption band near the solar F line (Fig. 23, p. 13). *Urobilinuria* the excretion of excess of urobilin may result from widely different causes, and as a consequence its clinical significance is not so clear as might be expected. The symptom is met with in connection with hæmolytic diseases, such as *pernicious anemia*, *malaria*, in *diseases of the liver*, such as *cirrhosis*, and in cases in which *excessive bacterial action* is going on in the intestine. It may also result from the use of certain drugs, for instance, *picric acid*. The bulk, if not the whole, of the urobilin of urine is derived from the intestine, where the allied *stercobilin* is formed by the action of the bacteria present upon *bilirubin*. *Stercobilin* is present in abundance in normal faeces, and urobilin in traces in normal urine. The test for it is given on page 407.

Uroerythrin—the highly unstable pigment to which the colour of pink urate sediments is due—when abundantly present in solution in the urine imparts to it a rich orange-red colour, which may even be mistaken for that due to blood. The colour is changed to a pale greenish-yellow by addition of an alkali. Hepatic derangements of almost all kinds, including the most trifling functional disturbances, may lead to the appearance of uroerythrin in the urine; but the most intensely pink urate sediments are seen in cases in which the liver

is the seat of pronounced morbid changes, such as cirrhosis, or the passive congestion due to cardiac disease.

Choluria. Urine which contains bilirubin has a rich orange colour with a greenish tint at the edge of the meniscus. The foam formed by shaking it has a yellow colour, whereas that of bile-free urine, even when deeply pigmented, is colourless. The colour of the urine may be much modified by the presence of biliverdin, in addition to bilirubin, and may approach to black or dark green.

The presence of bile pigment may be demonstrated by *Gmelin's test*. This is best carried out by allowing the urine to flow gently on to the surface of some nitric acid in a test-tube; on gently shaking, the familiar play of colours is seen at the junction of the liquids (*Fig. 321*, p. 406), and the urinary layer often retains the green tint of biliverdin for a considerable time. Again, a green ring is observed when diluted tincture of iodine is allowed to flow on to the surface of the urine in a test-tube (*Fig. 320*, p. 406).

When the quantity of bile pigment present is very small, the above tests may fail to reveal its presence, and *Huppert's test* may then be resorted to. A precipitate is formed by the addition, to a much larger volume of urine, of a solution of barium chloride and baryta water or of calcium chloride and lime-water; the precipitate, which carries down any bile pigment which may be present, is filtered off and washed into a test-tube with alcohol; dilute sulphuric acid is then added, and the test-tube is heated in a beaker of boiling water; if bile pigment be present, the acidulated alcohol acquires a rich green tint, due to biliverdin.

Choluria is merely a symptom of jaundice, but the appearance of bile pigment in the urine may precede any yellow coloration of the conjunctivæ or skin; or, as in cases of acholuric family jaundice, the skin may be tinted although the urine is free from bile pigment. In the very rare cases in which a fistula exists between the biliary and urinary tracts, choluria of pronounced degree has been observed, apart from any jaundice.

Certain drugs impart to urine a tint which, although yellow, is abnormal. This is seen when *santonin* is administered, or *chrysophanic acid*, which is a constituent of *rhubarb* and *senna*. In either case, the urine turns pink on addition of an alkali, but the pink colour is far more brilliant after santonin than after chrysophanic acid has been taken. Bright yellow urine may also result from the use, externally or internally, of *picric acid* (trinitrophenol) owing to the formation of *picramic acid* (di-nitro-aminophenol).

2. Pink and Red Urines. The conditions which lead to the excretion of a pink or red urine may be classified as follows: (*a*) Hematuria, in cases in which the blood pigment appears in the urine mainly as oxyhemoglobin; (*b*) Hemoglobinuria—usually in cases which do not belong to the paroxysmal class; (*c*) Porphyrinuria; (*d*) Administration of rosaniline as a drug; (*e*) Eating of sweetmeats coloured with eosin; (*f*) Presence of chrysophanic acid in an alkaline urine; (*g*) After the administration of phenolphthalein.

Hæmaturia and hæmoglobinuria. For the significance of these symptoms, and the detection of blood pigment in urine, the special articles dealing with them may be referred to (p. 347 and p. 357).

Porphyrinuria. Urine of a pink or port-wine colour may owe its tint to the presence in it of pigments of the porphyrin group, of which hæmatoporphyrin, formed by the action of powerful reagents upon hæmatin, is the most familiar example. Several such pigments are met with in the excreta, differing somewhat widely in their chemical composition though resembling each other closely in their absorption spectra. That which is present in large quantities in the feces of some porphyrinuric patients, the coproporphyrin of Fischer, or stereoporphyrin, is also found in small amounts in the urine, and the trace of porphyrin found in normal urine is of this nature. The chief pigment of the red urines is the uroporphyrin of Fischer. There is found also a dark pigment with no characteristic spectrum, called urofaecin.

Porphyrin in urine is recognized by means of the spectroscope. The condition is most liable to be mistaken for hæmoglobinuria, and the abnormal pigment sometimes shows a spectrum like that of oxyhemoglobin. If there is no albumin present, hæmaturia or hæmoglobinuria is excluded, and the addition of hydrochloric acid brings out the bands of acid porphyrin and not those of hæmatin.

The porphyrin is best extracted from such urines by the addition of 5 c.c. of glacial acetic acid to 100 c.c. of the urine, after which the porphyrin is precipitated on standing.

The several porphyrins may be distinguished by measurement of their absorption bands, or by preparation of the methyl-esters of the precipitated pigments and determination of their melting-points.

Acute porphyrinuria may result from the administration, usually over considerable periods, of *sulphonal* or allied drugs. It also occurs apart from the use of drugs, usually in association with abdominal pain and a form of ascending paralysis. In some cases the condition is congenital. The red urine may be passed from birth onwards, and the presence of porphyrins in the tissues renders them peculiarly sensitive to light; hence the observed association of persistent porphyrinuria with *hydroa aestivale* vel *vacciniforme*. In such cases the bones become stained deeply brown, and occasionally the teeth (*Fig. 111*, p. 126).

The acute toxic porphyrinuria, due to *sulphonal* and its allies, is almost confined to female subjects, but the congenital form, which is extremely rare, is, like other inborn errors of metabolism, chiefly seen in males, and sometimes in several members of a family.

Coloration by constituents of foods and drugs.—*Rosaniline*, which was at one time employed in the treatment of albuminuria, imparts a pink colour to the urine which, provided that it be known that the drug is being taken, offers no diagnostic difficulty. Aniline dyes have also, ere now, been deliberately added to the urine for the purpose of simulating hæmaturia.

Eosin has been employed extensively for the coloration of pink sweetmeats and lozenges, and the urine of those who eat such sweetmeats in considerable quantities acquires a rich pink colour and shows a brilliant green fluorescence. The nature of such pigmentation can hardly be mistaken by anyone who is aware of the fact that eosin is so employed.

Drugs which contain *chrysophanic acid* are used so frequently as aperients that this compound may rank as a common constituent of urine: and if, from any cause, the urine be alkaline, it acquires a pink or red colour, which may easily be misinterpreted. However, the history of the taking of rhubarb or senna, and the fact that the addition of an acid changes the colour of the urine to a bright yellow, renders the diagnosis easy. The pink colour which alkalis impart to the urine of patients taking *santonin* is so fugitive that it does not call for consideration here.

3. Brown and Black Urines.—The urine may be brown or black in the following conditions: (a) Jaundice; (b) Hæmaturia; (c) Hæmoglobinuria; (d) Porphyrinuria; (e) Indicanuria; (f) Melanuria; (g) Aleaptonuria; (h) Carboluria; and (i) After the administration of certain other drugs, such as *salol*, *salicylates*, *resorcin*, *gallic acid*, and *uva ursi*.

In some of the above conditions the urine has such coloration when passed; but in others, such as melanuria and aleaptonuria, the urine is usually of normal tint when freshly passed, and only darkens on standing in contact with the air.

Brown and black *jaundiced urine* is met with chiefly in cases of long-standing icterus, in which the skin has acquired a dull greenish tint, and the urine contains biliverdin as well as bilirubin.

In some of the early recorded cases of black urine, the colour was certainly due to *blood pigment*, and the smoky colour of many urines which contain blood pigment in the form of methæmoglobin is familiar to all. In *paroxysmal hæmoglobinuria* also the urine is not infrequently almost black. The ordinary tests for hæmoglobin, together with microscopic and spectroscopic examination, serve to reveal the nature of such cases (*Figs. 17 et seq.*, p. 13).

The urine of *porphyrinuria* may approach to actual blackness, owing to the abundant presence of purple pigments which have no characteristic spectra.

Indicanuria.—Urines which contain much indican may show no abnormality of tint; but occasionally, and especially in extreme cases, there are present in the urine, in association with the colourless indoxyl sulphate, other and higher oxidation products of indol, which impart to it a brown colour, intensified or developed on exposure to air. This variety of brown or black urine is recognized less than it should be, and it is probable that the condition has been mistaken not infrequently for melanuria. Such urine is not blackened, as that of melanuria is, by the addition of ferric chloride, nor by nitric acid in the cold, but does blacken when heated with nitric acid. The ordinary tests for indican reveal its presence in large amount. Thus, if a specimen of the urine be heated with an equal volume

of hydrochloric acid, and a drop of a dilute solution of bleaching powder, or a drop of nitric acid, it becomes black. If, after cooling, the dark-coloured liquid be shaken with chloroform, the latter takes up indigo-blue and -red and acquires a deep purple colour; but the supernatant liquid remains black. If the chloroform extract be separated and evaporated to dryness, the indigo-red may be dissolved out of the residue with alcohol, whereas the indigo-blue, which is insoluble in alcohol, may be taken up afterwards with chloroform.

Indicanuria signifies abnormal protein decomposition in the alimentary canal, brought about by intestinal bacteria; but it may also have its origin in collections of putrid pus, such as putrid empyemata.

Melanuria (Fig. 681). This is a symptom met with in some cases of *melanotic sarcoma*. The urine, when freshly passed, contains a colourless chromogen, melanogen, and usually has a normal tint. On exposure to air, it darkens quickly, owing to oxidation of the melanogen to melanin, becomes brown, and eventually quite black. When nitric acid is added to such a urine, it causes prompt blackening, even in the cold, and immediate blackening also follows the addition of a solution of ferric chloride. This is the most characteristic of the tests for melanuria. Bromine water produces a yellow or brown precipitate which quickly blackens. As a rule, melanuric urines, when treated with liquor potassæ and sodium nitroprusside, yield a deep Prussian blue on acidification with acetic acid, but this reaction is not due to the melanogen as such, is yielded by some other urines, and cannot be taken as diagnostic of melanuria.

It is stated that melanuria may be met with apart from melanotic growths, in cases of wasting and other diseases. Some of the cases quoted in support of this contention, and which were recorded before the more distinctive tests for the condition were known, were, in reality, examples of indicanuria, such as have been described above, and the writer has never met with true melanuria save in cases of melanotic sarcoma. Even in such cases it is not seen so long as the tumour is confined to its primary seat, but only when it has invaded the viscera, and especially the liver. Indeed, the quantity of melanogen excreted is apparently dependent upon the extent to which the liver has been invaded, and the amount of pigmentation in the growths of which it is the seat. Hence it happens usually that the diagnosis of the case has already been established before the peculiar pigmentation of the urine is developed.

Aleptonuria is the outward sign of a very rare anomaly of metabolism which is almost always congenital, and persists through life without any serious detriment to the health of its subjects. The peculiar properties of the urine are due to the excretion in it of an aromatic acid, homogentisic or hydroquinoneacetic acid, a product of katabolism of tyrosin and phenyl-alanin. It is, in all probability, a product of normal metabolism, which in normal individuals undergoes complete destruction.

Alepton urine seldom exhibits any abnormality of tint when passed; but darkens quickly on exposure to air, undergoing changes through brown to black, which resemble in the closest manner those seen in melanuric urines. However, the two conditions are distinguished readily by means of simple tests. When a dilute solution of ferric chloride is added to alepton urine, a deep blue colour appears for a moment, and reappears after each subsequent addition of the reagent, until oxidation of the homogentisic acid is completed. Unless the reagent be very dilute, oxidation occurs too rapidly and the blue colour is missed.

The addition of an alkali causes very rapid darkening, with absorption of oxygen, and heat increases the rate of blackening.

As homogentisic acid is a powerful reducing agent, alepton urines give some of the reactions of glycosuria. Fehling's solution is reduced freely with the aid of heat, but the blackening effect of the alkaline reagent gives a peculiar appearance to the reaction. No black precipitate is obtained with Nylander's reagent, but the alkali therein causes conspicuous darkening. The safranin reaction is not obtained, and alepton urine is optically inactive. An ammoniacal solution of silver nitrate is reduced rapidly even in the cold, a

Fig. 681. Melanuria.

reaction which is made use of for the quantitative estimation of homogentisic acid. It is because alcaptonuria is so rare, rather than because its recognition presents any special difficulty, that its properties are not widely known and not infrequently fail of recognition.

Carboloria.—A darkening of the urine, increased by exposure to air, is seen frequently after the administration of certain drugs which contain phenol, in *carbolic acid* poisoning, and as the result of outward application of carbolic acid. A carbolic acid compress applied to the head of a child for the destruction of pediculi quickly induces carboloria, and the taking of *salol* is another common cause. The urine has a smoky tint, or in cases of carbolic acid poisoning may be actually black. In the slighter cases it is best described as brown with a greenish tinge, and the meniscus, when seen from the side, appears black.

There is no direct chemical test for carboloria, and the diagnosis is usually based upon the knowledge that phenol, or some derivative or compound thereof, has been administered or applied. After boiling the urine for some time with Fehling's solution, a slight reduction is observed; but this is in no way comparable with that seen with alcapton urine. Indirect evidence is obtained by the addition of a solution of barium chloride, which in cases of carboloria produces a very slight precipitate or none at all. If, however, the urine be first boiled with hydrochloric acid, a precipitate is obtained such as is yielded by normal urines. This is due to the fact that, in the presence of abundant phenol and oxidation derivatives thereof, the sulphates of the urine are for the most part, or even wholly, combined as aromatic sulphates, which yield no precipitate with barium salts, whereas when the aromatic sulphates are broken up by hydrochloric acid a precipitate of barium sulphate is thrown down.

The diagnosis of the other varieties of brown or black urine which have their origin in the administration of drugs is based upon the fact that salicylates, or other drugs capable of producing such pigmentation, have been taken.

In some early cases of the condition called *ochronosis*—characterized by blackening of cartilages, deep pigmentation of regions of skin, a bluish-black coloration in the hollows of the ears, and pigment spots in the sclerotics—black urine of uncertain nature was passed, but in all more recent cases the ochronosis has been the outcome of alcaptonuria on the one hand, or of the application of carbolic acid to chronic ulcers over long periods on the other. In the latter case the urine may, or may not, show the dark tint of carboloria.

4. Green and Blue Urines. In some cases of jaundice the bile pigment excreted is so largely in the form of biliverdin that the urine has a dark green colour: but with this exception, practically all green urines met with in practice owe their colour to the taking of methylene blue, either as a drug or in sweetmeats. When the dose is small, the tint may be a rich green; but after larger doses, the urine is frankly blue. It is not always easy to account for the origin of such coloration of urine, for the patient may be quite unaware that he has taken methylene blue in any form, although examination of his urine may leave no doubt that he has done so. Sweetmeats are sometimes coloured with this pigment, as they are with eosin, and it is sometimes used to correct the colour of white sweetmeats. Again, a pill of methylene blue has before now found its way, either by accident or design, into a supply of pills of another kind. Absence of a known cause does not, therefore, by any means exclude this kind of pigmentation: and experience shows that unless it can be shown, by careful examination, that the colour of the urine is not due to methylene blue, it is needless to search for any other causation.

However, records are to be found of cases in which green urine was passed in days when the taking of methylene blue can be excluded, and the nature of the pigment in these is uncertain.

Although the green urine which follows the taking of methylene blue may appear perfectly limpid, the blue pigment is not held in solution but in suspension, and is, to a large extent, removed even by a single filtration. The green colour of the filtrate is greatly reduced, and the filter paper shows a blue stain. The pigment upon the filter yields a blue solution in chloroform, and if the chloroform solution, or the blue extract obtained by shaking the urine with chloroform, be shaken with liquor potassæ in a test-tube, the chloroform is decolorized and the supernatant alkaline liquid acquires a pink tint. The original urine, or the chloroform extract, shows an absorption band in the red of the spectrum which may be mistaken for that of indigo-blue.

There is no reason to think that indigo-blue ever produces a green or blue coloration of urine similar to that due to methylene blue : by the spontaneous breaking down of indoxyl-glycuronic acid, usually in alkaline urines, indigo-blue may be set free, and may form a dark blue sediment, or may impart a blue colour to the surface of a phosphatic deposit : and when, in the earlier years of the last century, indigo-blue was employed somewhat frequently as a drug in the treatment of epilepsy, a dark purple colour of the urine of patients so treated was observed : but under no circumstances are indigo pigments formed spontaneously in quantities sufficient to bring about such a result. *A. VARICOSE ABDOMINAL VEINS. (See VEINS, VARICOSE ABDOMINAL, below.)

VARICOSE THORACIC VEINS. (See VEINS, VARICOSE THORACIC, p. 910.)

VEINS, VARICOSE ABDOMINAL. The point at which distention of veins becomes varicosity is arbitrary ; most conditions that produce undoubted varicosity of the veins of the abdominal wall in some cases merely dilate them in others. When this dilatation is considerable (*Fig. 682*) it nearly always has much diagnostic significance, particularly

Fig. 682. Varicose thoracic and abdominal veins in a case of syphilitic mediastinitis of some years' duration. (See p. 910.)

if the direction of blood-flow is reversed. Veins, however, may seem to be dilated when they are but unduly visible owing to wasting of the subcutaneous fat ; or they may, in very rare cases, be simply varicose, like veins in the leg, owing to idiosyncrasy or hereditary predisposition. In neither of these cases, however, is the blood-current in them reversed. To test the direction of blood-flow, part of a vein should be chosen where there are no side branches, and the blood should be expressed from it by means of two fingers pressed down on the vein close together and then drawn asunder, whilst pressure over the vein is maintained by each ; when a length of the distended vein has been emptied in this way, one of the two fingers is taken off, and the time taken by the vein in refilling is noted ; the procedure is repeated, the other finger being taken off this time ; it is then generally easy to decide whether the vein fills from below upwards or from above downwards. Normally, the blood flows from above downwards in the veins of the lower two-thirds of the abdominal wall ; when the blood-flow is from below upwards there is almost certainly obstruction to the inferior vena cava, the blood which is unable to return by it find-

ing a collateral circulation via the superior vena cava.

Obstruction to the inferior vena cava is due to one or other of three main groups of conditions, namely :—

1. **Great general increase in the intra-abdominal tension**, owing to such conditions as : ascites : ovarian cyst : great splenic or hepatic enlargement.
2. **Thrombosis** without external obstruction.
3. **Obstruction by local compression**, specially by secondary growths in the retro-peritoneal glands.

When the obstruction of the inferior vena cava is due, not to the vein itself being thrombosed or invaded by new growth, but to the *general intra-abdominal pressure* becoming so great that the vein is, so to speak, flattened out, the varicosity of the veins upon the abdominal wall is but a late symptom, and the diagnosis will be made from the cause of the great abdominal distention, generally *Ascites* (p. 59) or a big tumour. If there is marked varicosity of the superficial veins early in a case of ascites the probability is that both are due to malignant disease.

When the inferior vena cava is obstructed by 'simple' thrombosis, the probability is that the clotting will not have started there, but will have extended to it from branches either in the legs or in the pelvis. Oedema of the legs will be a prominent symptom, and if a clear history is obtainable it may generally be ascertained that one leg became oedematous and painful before the other : when this is so it is suggestive of thrombosis starting in the saphenous or femoral veins of one side, the other leg becoming affected later when the clot has spread up through the iliac veins of the one side to the inferior vena, and thence down the iliac veins of the other side. The higher the thrombosis extends the higher up the back will the oedema spread : and when the renal veins have been reached, albuminuria, with tube casts, and even hæmaturia, may ensue. Ascites may also be present. Distention or varicosity of the veins of the abdominal wall will be of assistance in distinguishing such a case from one of acute or subacute nephritis, besides which there will be no oedema of the eyelids or face.

If there is no very tense distention of the abdomen : if the way the case began does not suggest thrombosis in one leg, or in the pelvis, extending upwards : and if, nevertheless, there is marked varicosity of the veins of the lower part of the abdominal wall, with the blood-flow in them reversed, so as to be from below upwards, the history being a relatively short one the probability is that the inferior vena cava is being obstructed by something that is in immediate contact with it. There will very likely be symmetrical oedema of the legs, and possibly albuminuria and hæmaturia. It is surprising how seldom an aortic aneurysm or other non-malignant mass obstructs a large vein sufficiently to produce this collateral varicosity : hence, the presumption is that such varicosity indicates *malignant disease*. It is worthy of note that carcinoma of the kidney is prone to extend into the renal veins and thus into the inferior vena cava by a process of direct extension (*Fig. 683*)

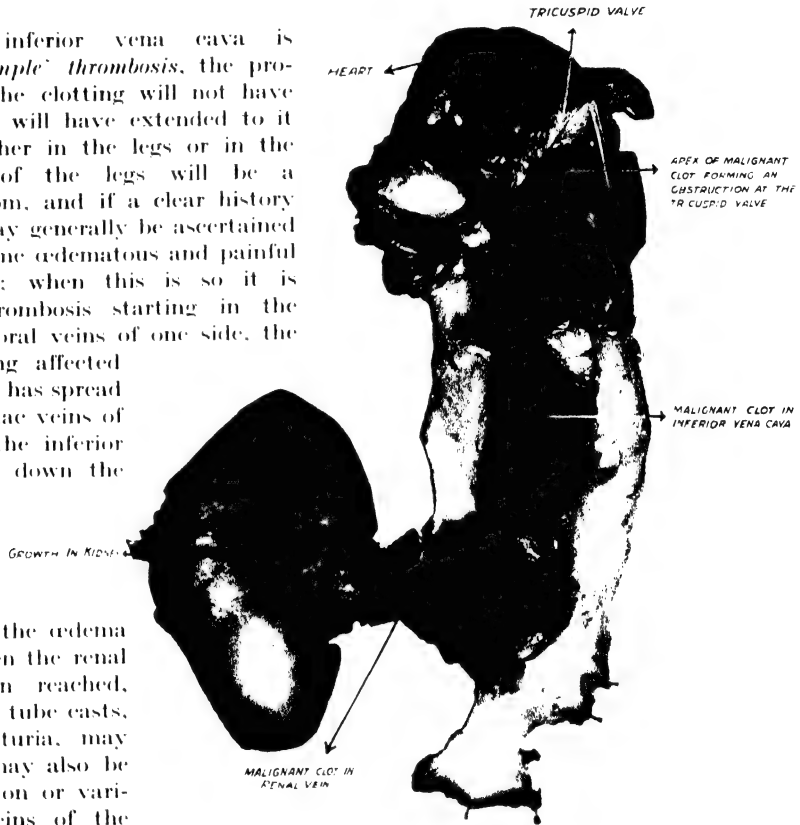

Fig. 683. Renal growth extending into the inferior vena cava and right auricle and ventricle.

—sometimes the malignant clot reaches as far as the right auricle, and produces a pedunculated polypus in the latter. In such cases there has generally been hæmaturia or other renal symptom before evidence of inferior vena caval obstruction arose, whereby cases of growth in the kidney invading the inferior vena cava may be distinguished from cases of secondary growth in the retroperitoneal glands, which if they produced hæmaturia at all, would do so by first obstructing the inferior vena cava, and thence involving the renal veins. In such cases there are often other symptoms pointing to primary growth in some organ whose lymphatics drain into the retroperitoneal glands: the testes and ovaries should not be overlooked in this respect.

It is often said that *cirrhosis of the liver* leads to varicosity of the veins around the umbilicus—the so-called *caput medusæ*. It is a very rare condition indeed, the great majority of cases of cirrhosis of the liver causing no distention of the superficial abdominal veins until such time as the general intra-abdominal tension has been greatly increased by the tenseness of the ascites which occurs late. Not even the telangiectases that occur so commonly in men past middle age around the lower part of the chest, in a line with the attachments of the diaphragm, indicate cirrhosis: they are quite as common in cases of emphysema without cirrhosis.

In short, varicosity of the superficial abdominal veins generally indicates either thrombosis of the inferior vena cava, secondary to direct spread of thrombosis up to it from veins in the pelvis or in the leg, or else stenosis of the vena cava by secondary malignant disease.

Herbert French.

VEINS, VARICOSE THORACIC. Much of what has been said above about varicose abdominal veins applies also to those of the thorax. The veins on the chest wall may

Fig. 684.—Skilagram from a case of syphilitic fibrosis of the mediastinum and left lung. The whole of the left thorax looks at first sight as opaque as if the pleural cavity on that side were full of fluid; but it will be noted that a little light comes through the central part of the left thorax, adjacent to the heart shadow; and the heart is not displaced to the right as it would be if the left-sided opacity were due to fluid. (*See Dr. J. H. Mather.*)

merely be unduly visible: but if they are really distended there is probably obstruction to one or other innominate vein or else to the superior vena cava: and the suspicion that this is so becomes a certainty if the blood current in the distended veins can be shown to be from above downwards instead of from below upwards. If the distention is bilateral, and associated with œdema of both arms and both sides of the neck, face, and head, it is the vena cava that is obstructed: if the distention is unilateral, with œdema of the corresponding arm, but little if any of the neck or face, the obstructed vessel is probably one innominate vein. The superficial varicosity may be only slight (*Fig. 218*, p. 260), but sometimes it is extreme.

In arriving at a diagnosis of the cause of the venous obstruction, *malignant disease* within the thorax will be uppermost in one's mind—especially mediastinal sarcoma, starting in the thymus or in the lymphatic glands. It is only when the history and course are too long for primary or secondary malignant neoplasm that other causes of venous obstruction will be regarded as more likely, such as *thrombosis* extending to an innominate vein or to the superior vena cava from a whitlow, boil, or other

inflammatory affection of the hand, arm, axilla, head, face, neck, shoulder, or front of chest: or *chronic fibrous mediastinitis*, sometimes tuberculous or gummatous (*Fig. 682*, p. 908; *Fig. 634*) but often rheumatic in origin, and resulting from repeated attacks of pericarditis and pleurisy, with matting together, not only of the pleura to the diaphragm and pericardium, but also of all the structures in the superior, posterior, and anterior mediastina to one another: or, far less commonly, to *aneurysm* of the thoracic aorta or a *non-malignant mediastinal tumour*, such as a hydatid cyst (*Fig. 298*, p. 366), a

dermoid cyst, or a large congenital fibroma, which may have been quiescent within the chest for many years before starting to enlarge and obstruct structures in its neighbourhood; the latter conditions, except aneurysm, are rarities, and although an aortic aneurysm does sometimes obstruct the superior vena cava sufficiently to cause distention or varicosity of the veins upon the chest wall, such varicosity is so much more marked in a case of intrathoracic malignant disease that one may say that when the diagnosis lies between neoplasm and aneurysm the presence of marked distention of the veins of the chest wall indicates the former rather than the latter, though the converse of this is not true.

Herbert French.

VERTIGO, popularly known as dizziness or giddiness, depends upon a disturbance of the sense of equilibrium. In slight cases the trouble is perceptible to the sufferer either as the apparent movement of motionless objects (objective vertigo), or his own body may appear to be moving in relation to surrounding fixed structures (subjective vertigo). In more severe cases it may lead to reeling or staggering, and unless the patient can grasp some fixed support he may fall.

The equilibrium of the body is maintained by the co-ordinated action of various groups of muscles, and the nervous mechanism for this co-ordination is situated in the cerebellum. Afferent impulses are brought to the cerebellar centres from the muscles, skin, joints, eyes, and the semicircular canals. The cerebellum is also connected with the motor centres of the cerebral hemisphere, and thus the requisite contraction of the necessary muscles is ensured. Disturbances of equilibrium may therefore be the result of a lesion in the cerebellum itself or in one of the afferent tracts. True vertigo depends mainly upon interference with the afferent impulses from the semicircular canals or from the eyes, and it is often accompanied by nystagmus during attacks.

Occasionally vertigo may be the result of altered cutaneous impulses due to such causes as anaesthesia of the soles of the feet. Some people experience a slight feeling of giddiness on stepping on to some soft material such as turf or india-rubber pavement after walking on a hard road. Unusual cutaneous impulses are the probable explanation.

Vertigo is sometimes divided into 'general' vertigo and 'special' vertigo. In the latter, objects appear to move, or the patient tends to fall, in a definite direction. Special vertigo points to a lesion of a particular semicircular canal. Thus, if there is a lesion of the external semicircular canal, objects appear to move in a horizontal plane, and the patient tends to fall towards the affected side. When the superior canal is the source of the trouble, objects rotate in a vertical plane, and the patient falls forward. Temporary vertigo, even of a very severe nature, may be produced readily in a healthy individual by prolonged movements of rotation or of swinging. In this case the cause of the giddiness is probably unequal pressure in the endolymph in the different semicircular canals. The dizziness with which many people are affected when near the edge of a high cliff is most likely ocular in origin, and depends upon the sudden cessation of visual impulses from near objects. Some persons are exceedingly susceptible to alterations in these impressions, and travelling by train or the movement of a boat may be sufficient to cause considerable dizziness.

Vertigo may also be of *toxic origin*. *Alcohol* and *tobacco* are familiar examples; the dizziness associated with *ptomaine poisoning*, in some cases of gastric disturbance, or as the result of chronic *toxæmia* from *dental sepsis*, *infected tonsils*, or *bowel troubles* is also probably of this nature.

Vertigo is not infrequently of cerebral origin, either with or without some gross lesion. Thus it occurs in *migraine*, and is also a frequent *aura of an epileptic fit*. Vertigo may depend upon alterations in the blood-pressure, and this is the probable explanation of its occurrence in *arteriosclerosis* and *nephritis*, where the blood-pressure is increased. It may also occur in cases where the blood-pressure is diminished, as in *Addison's disease*, some *anæmic states*, and during *convalescence* from any prolonged illness. This may be due to defective nutrition of the central nuclei. Attacks of vertigo occurring in elderly people with atheromatous arteries or suffering from *chronic nephritis* or *arteriosclerosis* must always be regarded as of serious import, since they may be the precursor of cerebral hæmorrhage or thrombosis. Severe vertigo may be one of the symptoms of a *cerebral*

tumour. It is more likely to be present when the growth is in the cerebellum, especially if the middle lobe is involved. A tumour involving the auditory nerve in its intracranial course will also give rise to this symptom. A *cerebral* or *cerebellar abscess* may also cause vertigo, but in this case there may also be suppuration in the middle ear, and the giddiness may be of labyrinthine origin. Optic neuritis should be looked for in every case of vertigo.

Vertigo may be of *ocular origin*. It is especially likely to occur when there is some lesion of the nerves or muscles leading to diplopia.

Laryngeal vertigo is a very rare condition: spasm of the glottis is accompanied by severe giddiness which causes the patient to fall down, and he may lose consciousness for a few seconds. Complete recovery ensues in a short time, but the attacks are likely to recur. This trouble may be of an epileptic nature.

Vertigo is, however, most commonly of aural origin, and is a frequent symptom of diseases of the ear, especially of the internal ear or labyrinth. In its most intense form it is one of the symptoms of *Ménière's disease*. Its onset is then sudden, and so severe that the patient may fall to the ground and even lose consciousness. Associated with the giddiness are severe tinnitus, and unilateral or bilateral deafness, while nausea, vomiting, and pallor of the face are frequently present. The vertigo passes off after a few hours or days, but impairment of hearing and tinnitus persist. The attacks tend to recur. Ménière's disease is probably caused by a sudden increase in pressure in the endolymph, and, in some cases at any rate, appears to be due to hæmorrhage into the semicircular canals. In some cases an embolism may be the cause. True Ménière's disease is very rare: but the occurrence of the symptoms, viz., vertigo, deafness, and tinnitus, in a less acute and sudden form, is by no means uncommon. They may be present without any obvious lesion of the middle or external ear, though sometimes there is some abnormality in one of these portions of the auditory apparatus.

Vertigo may be traumatic in origin, e.g., after a fracture of the base of the skull.

Syphilitic disease of the internal ear may produce symptoms closely resembling those of Ménière's disease, in that giddiness, tinnitus, and labyrinthine deafness are associated, the onset being quite sudden. Vertigo is, however, occasionally absent. The trouble is usually unilateral, and may occur in the secondary or tertiary stages. The diagnosis will depend on the history of syphilis or other evidences of the disease. Similar symptoms may occur in congenital syphilis, usually between the ages of ten and fifteen years, though occasionally much later. Eustachian-tube obstruction is usually present also, but treatment of this fails to improve the hearing, and other characteristic troubles, especially interstitial keratitis, may be found. Aural vertigo may also be associated with some lesion of the external or middle ear. Thus in the former case there may be a *foreign body*, or a plug of *impacted cerumen*, as the exciting cause.

Vertigo is not infrequently present in chronic middle-ear suppuration. This may be due to labyrinthine inflammation or irritation, but a definite labyrinthine lesion is not necessarily present. In many cases the giddiness is caused by pressure on the stapes or the fenestra rotunda. Some patients with a perforation of the tympanic membrane become giddy whenever the ear is syringed. Occasionally the use of unduly hot or cold lotions produces this trouble. It is usually the result of pressure on the stapes, though occasionally the vertigo may have the special character associated with a lesion of the external semicircular canal (*vide supra*). When this is the case there is probably some erosion of the bony external canal. Similar giddiness may occur from a like cause on syringing the ear after a radical mastoid operation.

Vertigo may occur in *otosclerosis*, though it is not common in this disease, and is always of less importance than the DEAFNESS (p. 205) and TINNITUS (p. 877). Gout and gouty dyspepsia, with or without evidence of arteriosclerosis, may also be the cause of attacks of vertigo.

When a patient complains of vertigo, the ears should always be examined carefully. The hearing should be tested, and if the cause of the trouble is in the labyrinth, the deafness will have the characters of nerve deafness (p. 208). The onset of the trouble must be investigated carefully, and any associated symptoms ascertained. The eyes and ocular muscles must be examined, and if nystagmus is present the character of the movements should be observed. A general examination should also be made for some general constitutional cause such as gout, albuminuria, or arteriosclerosis.

E. Farquhar Buzzard.

VESICLES. One of the primary lesions, the vesicle may be defined as a circumscribed epidermal elevation varying in size from a pin's head to a small pea, and containing serous fluid, which may become sero-purulent or be mixed with blood. Serous elevations larger than a small pea are classified as BULLÆ (p. 123). To bullæ, therefore, vesicles bear the same relation as papules bear to tubercles. They differ from bullæ, however, not only in size, but in their mode of formation. They are always the result of an inflammatory process, whereas in the case of bullæ there is a veritable cleavage of the epidermis. Vesicles, again, often contain a number of chambers, at any rate in the beginning, whereas bullæ are from the outset unilocular. They may originate as vesicles, or may develop from papules. Vesiculation may be either parenchymatous or interstitial. In the one case, as in varicella, the plasma accumulates *within* the Malpighian cells, and the unicellular vesicles which are thus formed run into each other. In the other case, as in eczema, the plasma accumulates *between* the Malpighian cells.

In shape, vesicles are usually rounded, conical, or acuminate: but they may tend to the oblong form, as in scabies, or they may be both oblong and irregular, as in dermatitis herpetiformis. The larger ones are occasionally umbilicated, as in variola, and instead of being tense, as is usual with vesicles, may be flaccid, as in herpes and dermatitis herpetiformis. At first the liquid they contain consists almost invariably of pure plasma, and is quite clear, or with the faintest tinge of yellow: but exceptionally the fluid is from the beginning mixed with blood. After a time the clear fluid becomes turbid. In some conditions, as in varicella and miliaria, they remain discrete and few in number; but usually, as in herpes, eczema, and dermatitis herpetiformis, there is a plentiful crop of them, forming groups or closely-set clusters. As a rule they are of short duration: either they rupture and crust over, as in eczema, or they dry up and a crust is formed, as is usual in herpes; or they enlarge into blebs, as frequently occurs in dermatitis herpetiformis; or they are transformed into pustules, as in variola. On mucous membranes and the lips, and in folds of the skin, they break more quickly than in other situations, and leave excoriations. Since, as already stated, vesicles are the result of a more or less inflammatory process, they usually give rise to much burning and itching, though in some conditions, as in hydrocystoma, these symptoms are absent.

The most distinctively vesicular affections are herpes simplex and herpes zoster. In *simple herpes* the face and the genital organs are affected chiefly. The characteristic lesion is a cluster of transparent vesicles varying in number from two or three to twenty or more, seated on an erythematous patch, and surrounded by a narrow red zone. First, a slightly red spot appears on the skin; effusion quickly takes place under the epidermis, and vesicles are formed; these become opaque—sometimes purulent—shriveled up, and form yellowish-brown crusts, which after a few days become detached, usually leaving no scar, but a brownish stain that slowly fades and disappears. These four stages in the evolution of the lesion are styled the congestive, vesicating, desiccating, and macular stages. On mucous membranes the lesion runs a rather different course. Here the vesicles are quickly reduced to a whitish pulp, which presents the appearance of a false membrane. When this becomes detached, it reveals a number of roundish excoriations, either scattered about irregularly or running into each other and forming largish ulcers. The favourite situations of the vesicles in herpes genitalis are, in men, the prepuce, especially its inner surface, the meatus, the sulcus, and the glans; in women, the labia and the cervix. In men, the vesicles are usually discrete, and the patient complains only of the itching and burning; but if they are neglected, or irritated by the application of caustics, there may be severe and extensive ulceration, with swelling of the inguinal glands. In women, the vesicles tend to become confluent, and the perineum, the inside of the thighs, and the mons veneris may be invaded. There may be a great deal of swelling, excoriation, and discharge, with intense itching and burning, and, as in men, there may be enlargement of the neighbouring glands. The vesicles of genital herpes are too characteristic to be mistaken if they are seen before their real significance is obscured by ulceration. If, however, the ulceration is considerable, and especially if there is much suppuration, the herpes may be mistaken for *chaneroids*. Generally, however, soft sores are multiple, have a fouler base, excavate more deeply, and the healing process is much slower. Soft sores, further, are flattened at the base, secrete very little liquid, and are auto-inoculable. In some cases there may be doubt as between herpes genitalis and true

chancre, especially as a chancre not infrequently develops in the midst of a premonitory eruption of herpes. The points of differentiation are the absence, in herpes, of induration, the less considerable and more transitory gland-enlargement, the multiplicity, irregular form, and small size of the ulcers, and the intense burning and itching.

In the crusted stage, facial herpes may resemble *impetigo*, but the rapid course it runs, its limited distribution, the facts that it is not auto-inoculable, and that in impetigo the lips are seldom attacked, should suffice to obviate the confusion. The points which distinguish herpes facialis from vesicular eczema are touched upon below.

In *herpes zoster* (zona, shingles), clusters of vesicles seated on an erythematous base appear in the region of skin distribution of one or more of the posterior spinal nerve roots, preceded or accompanied by neuralgic pain and tenderness in the part. The erythematous patches, more or less oval, with the long axis parallel to the underlying nerve, come out in crops, the number of lesions varying from two or three to twenty or thirty. Soon the surface of the patches is studded with papules, which are quickly transformed into vesicles, from ten to twenty on each patch, generally discrete, sometimes running into each other to form bullae. An important diagnostic feature of the eruption is, that in the great majority of cases it is unilateral, and appears much more frequently on the right side than on the left. In rare cases, however, it forms a complete girdle round the body. The

Fig. 685. — A case of fading herpes zoster of the lower branches of the right cervical plexus, showing the brownish staining left as the patches of grouped vesicles subside over the lower part of the neck, the upper part of the chest, and the shoulder and deltoid regions. A. Posterior view; B. Anterior view.

usual limitation to one side of the body, the distribution in one or more nervous territories (Fig. 685), and the preceding or accompanying neuralgia with glandular enlargement, usually suffice to distinguish herpes zoster from erythema multiforme and from dermatitis herpetiformis. Another important point in diagnosis is the history, for zoster is not a recurring disease. These various characters serve to distinguish it also from herpes simplex and herpes genitalis. The neuralgic pain may be mistaken at first for pleurisy, but the course the affection runs soon clears up the confusion. It should be added that in herpes zoster the forehead, the conjunctiva, and the eyeball are frequently attacked, and sometimes the mouth, especially the tongue. In rare cases the lesions on the tongue are associated with an eruption on the lips or the palate.

Although the vesicular stage is not, as some authorities consider, a necessary phase in the evolution of *eczema*, the vesicle is undoubtedly the most constant of all the primary lesions met with in that condition. Usually, following sensations of itching and burning, an erythematous blush appears, which is soon studded with numerous tiny vesicles. These grow larger and often coalesce, but they soon rupture or are broken by scratching, and a clear fluid exudes, the 'weeping' continuing as later vesicles break. In mild cases, the inflammation subsides gradually, and as the discharge ceases, scales or crusts are formed; but much more frequently fresh crops of vesicles start up around the edge of the earlier

patches, while new centres are formed in other parts, until nearly the whole cutaneous surface may be involved. In some cases papules are the predominant feature; in others erythematous lesions; in yet others pustules; and in extensive cases, the several kinds of lesions may be all present simultaneously. From herpes in general, eczema is distinguished by the characteristic exudation, by the crowds of tiny vesicles, which coalesce without forming distinct groups, by the slower evolution of the disease, and by the fact that as a rule there is some inflammatory thickening. From herpes zoster it is differentiated by the peculiar distribution of the vesicles in that affection (see above).

Acute vesicular dermatitis is precisely similar to acute eczema in its actual lesions, but differs from it in that a definite irritant cause exists and it does not recur, as does eczema, spontaneously, but only if the external cause is re-applied. The effect of certain plants, notably *primula obconica* and *rhus toxicodendron*, are familiar in this respect; also the vesicular eruption produced in some individuals by sugar (grocer's dermatitis), by the use of certain soaps (soap dermatitis), by the sawdust of satinwood, by the use of lime in making mortar, by various chemical substances employed in the manufacture of munitions, by the hairs of certain caterpillars, and by various applications and lotions (application dermatitis), including tincture of arnica montana, mesotan, essence of vanilla; and of course all the well-known vesicating drugs such as cantharides, croton oil, capsicum, mineral acids, caustic alkalis, strong iodine or turpentine, and so on. The diagnosis is afforded by a knowledge of exposure to any of these, and in obscure cases is sometimes suggested by the fact that exposed parts only are affected, or that the patient is ill only when living in certain places or doing certain work.

Dermatitis due to Plants. Below is given a list of plants which give rise to dermatitis, varying in degree from a simple erythema, sometimes accompanied by staining and generally itching, to a papulovesicular or in some cases a bullous or oedematous inflammation of the skin, the severity of the cutaneous symptoms depending on the toxicity of the offending substance, the duration of contact, and the susceptibility of the patient. The hands, forearms, and face are the parts most often affected. Doubtless many of these reactions are anaphylactic and in some cases hereditary. In a few instances, such as that of rose-picker's dermatitis, the symptoms may be due to slight mechanical injuries followed by septic infection, or to parasiticides such as carbolic acid, copper sulphate, or formalin, when they are more properly classed under occupational dermatoses. The diagnosis can generally be made by the history of exposure to the irritant, the acute onset, and the fact that, generally speaking, only exposed parts are attacked. These points will serve to distinguish plant dermatitis from erythema and eczema due to other causes.

Abies Canadensis and *excelsa* (Spruce)
Aconitum napellus
Actaea spicata
Allium sativum (Garlic)
Amacardium occidentale and *orientale* (Cardol)
Anacyclus pyrethrum
Anemone nemorosa (Wood anemone)
Anemone patens (Pulsatilla)
Angelica (Cow-parsley)
Antiaris toxicaria (Upas tree)
Aralia spinosa (Angelica tree, prickly elder)
Arisema triphyllum
Asparagus officinalis

Balsamum Gilead (Balm of Gilead)
Borago officinalis (Borage)
Bryonia alba (Tetterberry, Wild hops)

Cactus grandiflorus (Night-blooming cereus)
Calendula (Marigold)
Capsicum fastigiatum (Red pepper)
Cassinia aculeata (Australian dogwood)
Catalpa bignonioides (Indian bean)
Cephalis ipecacuanha
Chelidonium majus (Celandine)
Chimaphila umbellata
Chrysanthemum
Cinchona

Citrus vulgaris (Bitter orange)
Clematis Virginiana and *erecta*
Colchicum autumnale (Meadow saffron)
Cotoneaster microphylla
Croton tiglium
Cypripedium calceolus (Lady's slipper)

Daffodil (sap)
Daphne mezereum
Datura stramonium
Delphinium consolida and *staphisagria*
Digitalis officinalis (Foxglove)
Dirca palustris (Leatherwood)
Doronicum pardalianches (Leopard's bane)
Drosera rotundifolia

Erigeron Canadense (Flea-bane)
Eucalyptus hemiphloia (Australian gum-tree)
Eugenia pimenta (Pimento)
Euphorbia (Spurge)
resinifera
corollata
ipecacuanha
lathyris

Ferula galbaniflua
Ficus (Fig)
Gelsemium sempervirens

<i>Hedera helix</i> (Common ivy)	<i>Primula obconica</i> and <i>Primula sinensis</i> and <i>parinosa</i>
<i>Helleborus niger</i> (Black hellebore, Christmas rose)	<i>Pyrethrum roseum</i> , <i>carneum</i> , <i>cinariaefolium</i>
<i>Helianthus</i> (Sunflower)	Ragweed
<i>Heracleum lanatum</i> (Parsnip)	<i>Ranunculus sceleratus</i> , <i>bulbosus</i> , <i>acris</i>
<i>Hippomane mancinella</i> (Manchineel)	'Reed dermatitis', from chemical action of powder in leaves of old reeds (Timpanis) due to a fungus, parasitic upon <i>Arundo donax</i> (Gerbaud)
Hops	<i>Rhus metopium</i> (Coral sumac)
<i>Humea elegans</i>	<i>Rhus toxicodendron</i> (Poison ivy)
<i>Iris florentina</i> (Orris root)	<i>Rhus venenata</i> (Dogwood)
<i>Juniperus Virginiana</i> and <i>Sabina</i> (Savin)	<i>Rhus vernicifera</i> (Lacquer tree). Lacquer cabinets, Mah Jong sets, etc.
<i>Lappa officinalis</i> (Burdock)	'Rose-picker's dermatitis'
Laurel	<i>Ruta graveolens</i> (Rue)
<i>Leucanthemum vulgare</i> (Ox-eye daisy)	<i>Sanguinaria Canadensis</i> (Bloodroot)
<i>Lobelia inflata</i>	<i>Scilla</i> (Squill)
<i>Lycopersicum esculentum</i> (Tomato leaves)	<i>Sedum acre</i> (Stoncrop)
<i>Maruta cotula</i> (May-weed)	<i>Simplocarpus fetidus</i> (Skunk cabbage)
<i>Mucuna pruriens</i> (Cowhage)	<i>Sinapis alba</i> (Mustard)
<i>Myrcia acris</i> (Bay rum)	<i>Sisymbrium officinale</i> (Hedge mustard)
<i>Nasturtium armoracia</i> (Horseradish)	<i>Solidago</i> (Golden rod)
<i>Nerium Oleander</i>	<i>Stillingia sylvatica</i> (Queen's root)
<i>Pastinacea sativa</i> (Parsnip)	<i>Syringa vulgaris</i> (Lilac)
<i>Phytolacca decandra</i> (Poke, Garget)	<i>Thapsia garganica</i>
<i>Pilocarpus pennatifolius</i> (Jaborandi)	<i>Thuja occidentalis</i> (Arbor vitae)
<i>Piper nigrum</i> (Pepper)	<i>Tropaeolum majus</i> (Garden nasturtium)
<i>Podophyllum pellatum</i> (Mandrake)	<i>Urtica</i> (nettle), several varieties
<i>Polygonum aviculare</i> (Knot grass)	<i>Vanilla planifolia</i> (Vanilla)
<i>Polygonum punctatum</i> (Smart weed)	<i>Veratrum viride</i> and <i>album</i> .

Dermatitis due to Woods.

<i>Andira Araroba</i> (<i>Goa powder</i>)	<i>Gonioma Kamassi</i> (S. African boxwood)
<i>Antiaris toxicaria</i> (Upas tree)	<i>Tectonia grandis</i> (Teak)
<i>Chloroxylon swietenia</i> (East Indian satinwood)	Cocos wood, chestnut wood, and various species of mahogany are also reported to have caused dermatitis.
<i>Dalbergia latifolia</i> (Rosewood)	
<i>Diospyrus ebenum</i> (African ebony)	

Occupation Dermatitis.—A great many occupations may be the direct or indirect cause of cutaneous disturbances, generally as the result of repeated contact with some solid or gaseous substance which irritates the skin. In some cases there is a definite idiosyncrasy, in others excessive sweating inherited tendency, congenital susceptibility to the action of irritants as in ichthyotics, want of cleanliness and of careful removal of the irritating material on leaving work, are predisposing factors.

In many trades, e.g., laundry work, the dermatitis may be due to the general conditions of a hot, steamy atmosphere rather than to any particular chemical, such as bleaching powder: in gardeners it may be caused by exposure to the weather, moisture of the soil, etc., as well as by irritation from plants. The dermatitis varies from a simple erythema to a papular, vesicular, pustular, or bullous dermatitis, and is sometimes followed by or associated with ulceration or tumour formation. Staining of the skin may be present.

Trade dermatitis varies according to the particular substance which acts as the irritant. It may be due to one or several chemicals employed in the same trade. The hands, nails, and forearms are the parts most often affected, but other parts of the body may be reached by the irritant, e.g., various powders used in the manufacture of explosives. The list of chemicals which may lead to cutaneous irritation is being constantly extended with increasing knowledge and the introduction of new processes—the following list is far from complete. Such varieties of dermatitis as cotton-seed dermatitis, copra-itch (*Tryoglyphus longior*), grain-itch (*Pediculoides ventricosus*) which are due to animal parasites have not been included, nor the bacillary infections, e.g., anthrax,

glanders, tuberculosis, acute pemphigus, which are liable to be associated with certain occupations.

<i>Trade.</i>	<i>Chemical.</i>	<i>Nature of Eruption.</i>
Acetylene workers -	Carbide of calcium -	Eczema punched-out ulcers
Asphalt workers -	Tar -	Aene and furuncles
Bleachers and cleaners -	Chloride of lime -	Eczematous dermatitis
Barbers -	Soap, alkalis, dyes -	Eczematous dermatitis
Barmaids -	Water, soda, etc. -	Eczematous dermatitis
Carpenters -	Sawdust; teak, satinwood, etc. -	Eczematous dermatitis
Chemists -	Various substances, Phenyl-hydrazine hydrochloride -	Eczematous dermatitis
Chimney-sweeps -	Soot -	Eczema, warts, epitheliomata
Chlorine workers -	Chlorine -	'Chloric aene'
Confectioners -	Sugar, etc. -	Eczematous dermatitis
Coopers -	Caustic soda -	Eczematous dermatitis
Dyers -	Aniline dyes -	Staining. Irritant dermatitis
Fish and poultry dealers -	Various chemicals -	Chronic dermatitis
Flax spinners -	Sodium chloride, lime and calcium salts -	Erythematous-vesicular eruption
French polishers -	Bichromate of potassium -	Staining. Eczematous dermatitis
Glass-blowers -	Grease, resin, mechanical pressure -	Rhagades. Callosities on hands
Grocers -	Sugar -	Eczematous dermatitis
Leather tanners -	Yellow chrome -	Eczematous dermatitis
Masons -	Lime -	Chronic dermatitis
Munition workers -	(See below)	
Peat workers -		Warts
Painters -	Turpentine -	Irritant dermatitis
Paraffin and naphtha workers -	Crude oils -	Aene, pustular, ulcerous
Photographers -	Metol, pyrogallie acid, hydroquinone, amidol, rodinal -	Eczematous dermatitis
Printers -	Lye, benzine -	Eczematous dermatitis
Rubber workers -	Carbon bisulphide -	Eczematous dermatitis
Shellac workers -	Turpentine and arsenic -	Eczematous dermatitis
Silicate workers -		Eczematous dermatitis
Silk-winders -		Vesico-pustular eruption. Cellulitis
Silver- and electroplaters -	Mercury and potassium cyanide -	Vesico-pustular eruption. Cellulitis
Tanners -	Various chemicals -	Chronic dermatitis. Ulcers
Tar-workers -	Tar products -	Eczema, warts, epithelioma
Washerwomen -	Soap and soda -	Chronic dermatitis. Ulcers
Wet-winders -	Potash, alum -	Acro-asphyxia.

The chief substances employed in the making of explosives and liable to cause dermatitis are: Picric acid (lyddite, melinite), dinitrophenol, tetryl (high-explosive shells), hexanitro-diphenylamine (bombs), trinitrotoluene (ammonal), fulminate of mercury (detonators), barium salts (Verey lights), dichloro-diethylsulphide (mustard gas).

Dermatitis due to Local Application of Drugs. The following list gives some of the drugs and chemical preparations most liable to cause vesicular dermatitis: -

<i>Drug.</i>	<i>Nature of Eruption.</i>
Aconite -	Erythematous-vesicular erysipelatoïd eruption
Antimony -	Varioloid eruption
Arnica -	Erythema, vesication, erysipelatoïd eruption
Arsenic -	Erythematous dermatitis
Atropine -	Scarlatiniform erythema
Balsam of Peru -	Erythematous, urticarial, or eczematous eruption
Belladonna -	Erythema, vesication
Cantharides -	Erythema and vesication
Capsicum -	Erythema
Chlorine -	Aeneiform eruption and ordema with exfoliative dermatitis
Chrysarobin -	Erythema and staining
Formalin -	Urticaria, eczematous eruptions
Hydrogen peroxide -	Erythema and vesication

Drug.	Nature of Eruption.
Iodine - - - -	Erythema and staining, with desquamation
Iodoform - - - -	Erythema, vesication, purpura
Mercury - - - -	Erythema, pustular folliculitis
Mesotan - - - -	Erythema
Mustard - - - -	Erythema, vesiculation
Oleum cadini - - - -	Erythema and folliculitis
Oleum crotonis - - - -	Erythema, pustular folliculitis
Orthoform - - - -	Erythema, gangrene
Paraphenylenediamine - - - -	Erythematous and eczematous dermatitis
Pyrogallie acid - - - -	Acute erythema and edema
Phenol - - - -	Erythema, eczematous dermatitis, necrosis
Phenol-hydrazine hydrochloride - - - -	Erythema and vesication
Salicylic acid - - - -	Vesicular eruption
Sulphur - - - -	Erythematous and eczematous dermatitis
Tar - - - -	Folliculitis
Turpentine - - - -	Papular erythema, vesicles and bullæ.

Doubt can seldom arise as between eczema and *dermatitis herpetiformis*. It is true that the earliest and perhaps the most characteristic lesion of the latter disease is a vesicular eruption, appearing on an erythematous base; but the disposition of the vesicles in herpetiform groups should prevent confusion between the two conditions. The vesicles soon dry up and form scabs, but later they tend to coalesce into bullæ, which scarcely ever burst spontaneously, but, as their contents thicken, slowly shrink, and finally, if left to themselves, shrivel up to a thick brown scab. The 'weeping' of eczema is therefore absent in dermatitis herpetiformis, of which, further, multiformity is a more pronounced feature—erythematous, vesicular, pustular, papular, and urticarial elements being mingled in all stages of evolution. Eosinophilia is more pronounced with dermatitis herpetiformis than it is with eczema (p. 126).

The vesicles of *impetigo contagiosa* are distinguishable from those of eczema by the larger size and discrete character of the former, and by their tendency to dry and form yellowish crusts without breaking, or as soon as they have broken. Even when the lesions run together and large crusts are formed there will be discrete vesicles and papules which will point to the true nature of the affection.

Miliaria rubra may sometimes resemble the vesicular stage of eczema, but here again the lesions, though numerous, remain discrete: they do not run together to form patches, they do not rupture, and there is no 'weeping.' Miliaria of all forms is a very transitory affection, and instead of the intense itching of eczema, the patient describes his sensations as those rather of prickling and tingling. In the form of miliaria known as hydrocystoma, or dysidrosis of the face, palms, or soles, small vesicles appear situated more in the substance of the skin than on it, and so grouped as to form patches which show no tendency to spontaneous involution: they itch, and when scratched they discharge the retained sweat as a clear watery fluid.

Scabies is another affection in which the vesicles, like those of impetigo and of miliaria, are discrete. Sometimes the lesions, usually consisting of papules and pustules as well as of vesicles, take on an eczematous character, but they are not localized as are those of eczema, and instead of being small, acuminate, or circular, they tend to be linear. In uncleanly persons the burrows between the fingers and elsewhere which mark off scabies from all other affections can hardly be overlooked. When they cannot be found, either because they have not yet been formed or because they have been laid open by scratching, the diagnosis of scabies must rest upon the irregularity of the lesions—vesicles, bullæ, and pustules being mingled with the marks of the finger-nails and the results of secondary inoculations—and upon the distribution, the parts most affected being those where the skin is least thick, namely, the webs between the fingers and toes, the front of the wrist, inside the umbilicus, on the lower abdomen, the genitalia, the nipples in women, and the axillary folds. The face nearly always escapes, except in infants in arms.

Another vesicular condition in which the hands are specially attacked is *cheiropompholyx*, in which numerous minute vesicles deeply imbedded in the skin, and showing through the epidermis like boiled sago-grains, are distributed symmetrically on the palms and fingers, and frequently also on the soles and toes. The general features of

the affection—the limitation of the vesicles to the hands and feet and their proneness to unite and form bullæ which dry up, the tendency to recovery followed by repeated recurrence, and the constant association of the eruption with the summer season—are sufficiently distinctive, and the diagnosis is seldom in doubt. In some slight cases there is a general resemblance to certain subacute and limited cases of eczema in which the lesions may present the sago-grain aspect: but instead of rupturing and ‘weeping’, the vesicles in cheiropompholyx tend to run together into bullæ, which shrink and crust over. This formation of bullæ by coalescence of vesicles differentiates the condition also from pemphigus.

In *erythema multiforme* the vesicle can seldom be difficult of interpretation, even in *erythema iris*, or as it is also styled, *erythema vesiculosum*. In one form of this affection a small red spot appears, upon which is formed a vesicle that is quickly surrounded by a zone of redness. When the central vesicle dries up it leaves a small scab, and a ring of secondary vesicles soon appears on the red zone. On the separation of the central scab the skin beneath has a blue, congested appearance. The whole process may be repeated time after time until the concentric rings of vesicles and reddened skin suggest comparison with a target. In the form of *erythema iris* which sometimes is infelicitously called *herpes iris*, a large central bulla is encircled by vesicles of considerable size. Outside the first ring of vesicles another circle may develop, and outside the second sometimes a third. The symptoms of vesicular erythema multiforme are so characteristic that the affection can hardly be mistaken for anything else.

Lichen planus is so characteristically a papular affection that the absence of vesicles is one of the points which distinguish it from eczema. In some cases, however—very rarely in adults, rather less infrequently in children—vesicles appear, but never so as to confuse the diagnosis. In *lichen urticatus* a vesicle appears on the summit of the small wheal, and the condition may offer some resemblance to eczema; but the individual lesions do not tend to run together nor to spread centrifugally, as in eczema, and the itching is usually more intense.

The vesicular form of *secondary syphilis* is so rare that by some authorities its existence is not recognized, and Stelwagon justly points to the possibility of its being due, at any rate occasionally, to drug idiosyncrasy. The vesicles are reported as occurring in several forms: they may be minute, eczematoid, disseminated and grouped, or larger, irregularly scattered, or disposed in herpetiform groups; and cases have been reported which simulate herpes zoster. The vesicles in syphilis are usually associated with papules, and they have a papular base, the disappearance of which leaves a long-persisting dark stain. The papular base and the slow evolution are important diagnostic points; and usually other signs of syphilis will be present.

In *lymphangioma circumscriptum*, even more than in vesicular syphilis, the significance of the vesicles can hardly be missed. In circumscribed areas of the skin there is an eruption of clusters of small, deep-seated, thick-walled vesicles, straw-coloured, sometimes marked with red striae, and filled with a clear alkaline fluid which contains a few lymph-corpuscles. The affection, which consists in the over-growth and dilatation of lymph-vessels and the formation of new ones, is probably congenital, though not generally noticed until early childhood.

Varicella—to come to the eruptive fevers—is an essentially vesicular affection: only occasionally do the vesicles develop into pustules. They are usually preceded by reddish spots of slight elevation, and the commonest situations are the face, chest, shoulders, back, and scalp, but they may also be found on the mucous membrane of the palate, mouth, or lips. As a rule the rash comes out within twenty-four hours. Often there is but trifling systemic disturbance. In the infrequent cases in which the varicellar eruption becomes pustular, it may possibly be confused with a pustular syphilide; but in the syphilide the lesions are pustular from the outset, or develop out of papules, and although the lesions of varicella start as papules, these are almost invariably small and evanescent. The absence of itching in syphilis is another point of difference. In exceptional cases of *lichen urticatus* the vesicle on the summit may develop until it becomes visible macroscopically, and it may then be confused with varicella.

It is with *small-pox* that chicken-pox is most often confused. In small-pox the vesicles are usually multilocular; in chicken-pox, unilocular. In small-pox they are

frequently umbilicated; in chicken-pox they are never umbilicated, and seldom even dimpled. The differences between the two exanthems in respect of the rash and the lesions generally, as summarized by Ricketts in "The Diagnosis of Small-pox," are these: In variola the rash is most abundant on the face and limbs (*Fig. 686*), and least abundant on the chest and abdomen; in varicella the abdomen and chest are covered as thickly as the face, if not more thickly. In variola the rash is much more abundant on the back than on the abdomen; in varicella the abdomen and the back receive equal attention. In variola the rash is more abundant on the shoulders than across the loins,

Fig. 686. Mild discrete small-pox: showing the distribution of the eruption, the face and limbs being affected more than the chest and trunk; over the limbs (arms) the pustules tend to be more numerous distally than proximally—the centrifugal distribution of the small-pox eruption in contradistinction to that of varicella. (*Fig. 10, II, "Smallpox."*)

and on the chest than on the abdomen; in varicella the distribution as between these parts is indifferent. In variola the rash favours the limbs and is distributed centrifugally (*Fig. 686*); in varicella it tends to avoid the limbs, and when it invades them is centripetal. In variola the rash, unlike that in varicella, favours prominences and surfaces exposed to irritation, and tends to avoid protected surfaces and depressions. As to the lesions generally, in variola they are deep-seated and have an infiltrated base; are generally circular in outline and homogeneous in character; whereas in varicella they are superficial and have no infiltrated base, are frequently irregular in outline, or else oval or elongated, and are not, as a rule, homogeneous.

Vaccinal eruptions may consist (1) of tiny vesicles or small superficial papules, or of a combination of those elements; or (2) of a small papule with a vesicular or pustular head. In the second case the eruption may simulate modified small-pox, but almost always the vaccinal lesions are more superficial than those of the mildest cases of small-pox, and show a preference for the trunk.

In eruptions due to the use of *bromides*, *iodides*, and other *drugs*, the vesicle is but one of the elements, and the nature of the affection is usually indicated with sufficient distinctness by the history of the case, the remission that occurs when the drug is withheld, and the recurrence that takes place when its administration is resumed. Vesicles that follow the *bites* or *stings*

of *gnats*, *mosquitoes*, etc., are always easily recognizable from the history, and from the central punctum to be seen in the lesions; nor can there be any doubt as to the significance of those due to such accidental causes as *frostbite* and pressure from *splints*.

Ernest Dore.

VISION, DEFECTS OF. This subject may be considered in the following order: (I) *Normal vision*; (II) *Amblyopia*; (III) *Partial blindness*; (IV) *Complete blindness*; (V) *Defects in colour vision*; (VI) *Abnormal sensations of size*; (VII) *Day- and Night-blindness*.

I. NORMAL VISION.

1. Visual Acuity. The act of vision comprises the perception of form, colour, and brightness; and, in vision with two eyes, the perception of space and distance. These faculties are possessed by all parts of the retina, though in varying degrees, and they are of varying importance. It is necessary to distinguish between peripheral and central vision; or, in other words, between merely seeing a thing and looking at it. An object is seen by any portion of the retina that has visual perception; but an object is only looked at when its image falls upon a particular portion of the retina, the yellow spot, which is situated at

the posterior pole of the globe on the outer side of the optic disc. The act of so directing the eye that the image of a given object shall fall upon the yellow spot, is termed 'fixation'. The vision obtained by the fixation of the eye is termed 'central vision', and owing to the anatomical structure of the retina at the yellow spot, the vision here is the most acute of which the eye is capable, though its area is very limited. In the normal eye, central vision is capable of distinguishing two points or parallel lines which are separated by a space which subtends an angle of $1'$ —approximately the diameter of a sixpenny-piece at 200 feet—and it is on this basis that ordinary test-types are constructed. Central vision, however, though acute, is very limited in extent, and it is estimated that the field of acute vision is only about the size of the thumb-nail held at arm's length, all vision outside this area being comparatively blurred and indistinct. This limitation of the field of acute central vision is barely appreciated under ordinary circumstances, owing to the rapidity with which the retina receives consecutive visual impressions, and the constant movements of the eyes. Compared with the visual acuity of the central portion of the field of vision, peripheral vision is relatively poor, though it is of extreme value in a different way. To appreciate the importance of peripheral vision it is only necessary to try to walk about looking through a roll of music: though central vision is unimpaired, and the smallest object can be seen distinctly, locomotion is almost impossible, owing to the inability to see where one is going or to ascertain one's position in relation to surrounding objects, the peripheral portion of the field of vision being responsible for the automatic appreciation of these. On the other hand, a person from some cause deprived of central vision can see to get about quite well, and has useful vision for many purposes, though he is unable to read or write, recognize people when looking directly at them, or do any work in which fine vision is required.

2. Colour Vision. A person with normal colour vision can recognize six or seven distinct colours in the solar spectrum, and is able to appreciate many hundreds of varieties of colour caused by mixtures of them, and the colour perception of the normal person is most acute in the central portion of the field: but the field of vision for colours under equal illumination has by no means the same boundaries as the field of vision for white. The fields of vision for all colours are smaller than that for white, and the fields for red, green, and blue vary in extent among themselves. The field for blue is the largest, for red is next in point of size, and the field of vision for green is the smallest of all, being roughly only about half to a third the diameter of the field for white.

3. Brightness Perception. The central and peripheral portions of the field of vision vary very much in their perception of brightness. In ordinary illumination the central portion of the field is the most efficient, but in a very weak illumination the peripheral portion has a higher efficiency than the central part: in other words, there is in very dim lights a relative central scotoma or loss of vision. This fact has long been known to astronomers, who have found that in counting stars of low magnitudes, vision is much better if the particular constellation or group of stars is not looked at directly, the Pleiades being a well-known example: more of these stars can be counted when the vision is directed to a point a little above or below them or to one side, whereas on absolutely direct vision they are comparatively dim and confused: and the same holds good of vision for any object in a dim light. Walking along a country road on a dark night, it will be found that a footpath or track can be seen more easily if the gaze is directed forwards and not at the ground itself. These facts concerning vision may be correlated with the actual anatomical structure of the retina itself. It is found that in the region of the yellow spot—the area of the retina endowed with acute vision—the cones are very numerous, with few rods: towards the periphery of the retina the cones become fewer and the rods more numerous. It is now generally held that the function of the cones is to work in light of considerable brilliance, that they are capable of extremely acute vision for small objects, and are also concerned in the perception of colour. The rods, on the other hand, have no perception of colour: their perception of form is poor compared with that of the cones: but in very weak lights their visual acuity is greater than that of the cones. In support of this theory may be mentioned the fact that the retine of owls and nocturnal animals are more fully provided with rods than cones.

II. AMBLYOPIA.

Amblyopia is the term applied to defective vision in which there is little or no evidence of any ocular condition which might account for the visual defect. It is not, therefore, employed where there is any obvious intra-ocular or intracranial lesion. The commoner forms of amblyopia are : (1) Amblyopia ex anopsia : (2) Uræmic amaurosis : (3) With nystagmus : (4) Due to alcohol, tobacco, lead, quinine, organic forms of arsenic such as atoxyl or salvarsan and its allies : (5) Migraine : (6) Cortical or crossed amblyopia : (7) From severe hæmorrhage : (8) With hysteria.

1. **Amblyopia ex Anopsia** is usually associated with a squinting eye, which may or may not have been put straight by operation. It is still open to discussion whether the amblyopia in such conditions is due to the loss of use by reason of the squint, or whether the squint is due to the visual defect : but the fact remains that in many squinting eyes the visual acuity is very much below normal, though objectively the eye exhibits no abnormal symptoms.

2. **Uræmic Amblyopia, or Amaurosis**, may be recognized by its association with renal disease, whether complicated by pregnancy or not. It is characterized by its comparatively sudden onset, vision failing either partially or completely within a few hours. The failure of vision may be accompanied by well-marked retinitis in both eyes : but in many cases this is absent and the discs appear quite normal. The failure of vision lasts for from thirty-six to forty-eight hours, and then slowly disappears, the whole attack lasting, as a rule, under a week. In the majority of cases, unless there is some definite injury to the optic nerve or retina as the result of retinitis, the vision recovers entirely. In some cases of uræmia the blindness is complete.

3. **Amblyopia with Nystagmus** is usually associated with evidence of visual affections in very early life. At birth, fixation is not developed, and the higher visual acuity is only acquired after the first few months of infant life. Any affection of the eyes, therefore, that obscures the vision during the earlier weeks or months of life, prevents the due development of central vision and leads to a permanent amblyopia, as a rule associated with nystagmus. Such affections are ophthalmia neonatorum, which leaves more or less corneal opacity : perforation of the cornea with anterior polar cataract as the result of this ophthalmia : congenital defects, such as a persistent hyaloid artery or macular coloboma : and any retinitis or choroiditis affecting the region of the yellow spot.

4. The **Amblyopia due to Lead, Alcohol, Tobacco, Quinine, or Atoxyl** is usually described as a toxic amblyopia, and the symptoms are somewhat similar in all the varieties. In tobacco amblyopia there is a central loss of vision for colours, green only in the earlier stages, subsequently green and red, and in extreme cases even a central scotoma for white : total blindness is practically unknown. The patient also states that he sees better in a dull than in a bright light, and that he is incapable of reading or writing, or distinguishing silver from gold coins. The ocular signs are usually very slight, being limited to some redness and blurring of the optic disc in early cases, or pallor of the outer side of the disc in later stages. Alcoholic amblyopia resembles in most of its symptoms the amblyopia due to tobacco, though vision for red is usually lost before vision for green. Amblyopia due to lead or atoxyl is rare, but it is also usually characterized by a central scotoma associated with some slight optic neuritis or atrophy. In quinine amblyopia the retinal vessels are extremely constricted, the disc is pale, and the field of vision is diminished peripherally.

5. The **Amblyopia of Migraine** is usually transitory, and may occur either in the form of a central scotoma, hemianopsia, or monocular blindness. It is more rarely seen in the form of a quadrant hemianopsia or a ring scotoma. In all cases the diagnosis is fairly easy, as the amblyopia seldom lasts more than a few minutes, and is followed later by the characteristic headache and sickness of migraine, sometimes with fortification figures, flashes of light, and other subjective phenomena in the fields of vision.

6. Amblyopia has also been described as due to **Disease of the Visual Cortex**, and rare cases have been described of a **Crossed Amblyopia** or defect of vision in one eye due to disease of the visual cortex of the other. The loss of vision is, however, usually associated with some slight defect of vision in the opposite eye, and hemianopsia is much more commonly the symptom of disease of the visual cortex.

7. Amblyopia due to **Severe Hæmorrhage** is familiar to those, for instance, who have attended cases who have nearly died from post-partum hæmorrhage, or blood loss from placenta prævia: it may also result from any other severe hæmorrhage—gastric or duodenal ulcer, hæmoptysis, epistaxis—the patient complaining that everything seems dark, though it may be broad daylight.

8. **Hysterical Amblyopia** may, like other hysterical affections, take various forms such as loss of visual acuity, a loss of colour vision, or diminution in the visual field. The characteristic form of the visual field in hysteria is either a spiral contraction or an extreme concentric limitation. The symptoms, however, vary very much at different examinations, a point of much importance in diagnosis. In certain cases there may be a functional loss of vision in one or both eyes, which can be recognized as hysterical by the employment of Snellen's coloured types or some other device for deceiving the patient.

III. PARTIAL BLINDNESS.

This may be: (1) *Definite*: or (2) *Indefinite*.

1. **Definite.** (a) *Hemianopsia*; (b) *Central scotoma*; (c) *Peripheral constriction*.

a. *Hemianopsia*, see p. 377.

b. *Central Scotoma*. A scotoma is a local defect in the visual field, and, from its position, may be either central or peripheral: it may also be negative or positive. A negative scotoma is one where the defect of vision exists, but where the patient has no abnormal visual sensation. Sight is merely absent over that area. The best example of a negative scotoma is the blind spot in the field of vision caused by the entrance of the optic nerve. This area is blind, but the individual is not conscious of any visual defects. Scotomata of this character exist where there is some injury of the visual layers of the retina itself, or of the optic nerve or tract.

A positive scotoma is one in which the visual defect is noticed as a black or coloured spot or cloud which obscures the vision in some part of the visual field. Such positive scotomata are due to lesions of the retina, such as hæmorrhages or patches of pigment, which do not destroy the visual layers. Vision still remains, but is obscured by some unusual opacity in the retina itself or in the adjacent portion of the vitreous.

Scotomata frequently exist in the peripheral portion of the field of vision without being noticed, as they are of little importance in direct vision, and are not discovered unless looked for carefully. A central scotoma, on the other hand, is noticed at once, however minute, because it affects direct vision and produces a considerable defect in the visual acuity. A central scotoma may be either relative or absolute, and may exist for colours only or for objects. Central loss of vision for colours, more particularly red and green, is associated with *tobacco* and *alcohol poisoning*. The colours cannot be recognized in small objects when looked at directly, though a red or green object in the peripheral portion of the field of vision will be recognized as such. This scotoma is associated with greater or less diminution of the general visual acuity, and vision in such cases is generally better in a dull than in a bright light.

Absolute central scotomata are met with in *disseminated sclerosis*, in certain forms of *hereditary optic atrophy* (Leber's atrophy), and may persist after the acute affection of the optic nerve known as *retrobulbar neuritis*, or in rare cases after severe attacks of *migraine*. They are also sometimes found in the early stages of compression of the optic chiasma by a pituitary tumour. *Lead poisoning* is also a possible cause. In nearly 25 per cent of all cases of disseminated sclerosis a central scotoma exists, and the diagnosis in such a case will be confirmed by its association with the general symptoms of the disease, especially intention tremor, extensor plantar reflexes, exaggerated knee-jerks without sensory disorder, and with other ocular symptoms, such as optic atrophy, paralysis of accommodation, paralysis of the extrinsic ocular movements, or nystagmus. There is usually some pallor of the optic disc, though this is no indication of the amount of visual defect. The diagnosis of an *hereditary optic atrophy* (Leber's atrophy) depends to a great extent upon the history of a similar affection among family relations and its usual period of incidence, namely, early adult life. It is associated with either neuritis or, more commonly, atrophy of the optic disc. *Retrobulbar neuritis* usually occurs in young adults, commonly attacks one eye only, and is sudden in its onset, vision failing from normal to

no perception of light in a few hours. In the great majority of cases vision commences to return after the lapse of a day or two, and is ultimately restored in a fortnight or three weeks. If any defect remains it is usually central, and is due to some injury to those axial fibres of the optic nerve which supply the macular region. Its pathology is obscure, but it may be associated with infections of the ethmoidal or sphenoidal sinuses. Central scotomata after *migraine* are rare, but may be ascribed to that cause when there is a definite history of sudden loss of sight associated with the characteristic hemicrania and vomiting. It is to be noted that central scotomata are not always easy to map out on a chart, owing to the patient's loss of power of fixation: a careful use of the perimeter by an experienced observer is necessary. A small central scotoma may cause considerable failure of vision, even though it is too small to chart on the ordinary perimeter. Scotomata may also be *para-central*, in the immediate neighbourhood of the fixation point, but not actually upon it, or may take an *annular* or *ring form* as in some cases of *choroiditis* or early *chronic glaucoma*.

c. Peripheral Constriction. Peripheral constriction of the visual field occurs commonly in affections such as acute or chronic *glaucoma*, *optic atrophy*, *disseminate choroido-retinitis*, *retinitis pigmentosa*, and various *functional conditions*. The constriction of the visual field in *glaucoma* is usually most marked on the nasal side, and can be recognized from its association with the acute symptoms of glaucoma, the circumcorneal injection, steamy insensitive cornea, dilated fixed pupil, hazy vitreous, and general symptoms such as trigeminal neuralgia, headache, and sickness. In chronic glaucoma it will also be associated with atrophy and cupping of the optic disc (*Fig. 428*, p. 520). Central vision may remain quite good, even though the field of vision is extremely limited. The field of vision is, as a rule, most limited in *retinitis pigmentosa*, where the failure of sight will be found to be associated with night-blindness and characteristic ophthalmoscopic appearances, a small, ill-defined, waxy-looking disc, slender vessels, and diffuse superficial pigmentation of the periphery, the retina in patches resembling Haversian bone corpuscles. This condition often occurs in two or more members of the same family, and may exist where the parents have been first cousins. A limitation of the field similar to that of retinitis pigmentosa is often met with in cases of *disseminate choroido-retinitis* (*Fig. 415*, p. 518) and consequent optic atrophy; but may be distinguished from it by abundant evidence in the eye of deeper changes in the retina and choroid. Constriction of the field of vision may also occur in certain *functional states*, but may, as a rule, be recognized by its variable character and the absence of all evidence of organic ocular or general nervous disease.

2. Indefinite.—A defective visual acuity may exist with no evidence of any ocular or nervous disease (see *AMBLYOPIA*, p. 922). Defective vision may also be due to errors of refraction, to opacities of the cornea, aqueous, lens, or vitreous, to affections of the choroid and retina, and to lesions of the optic nerve. Opacities of the cornea can easily be recognized on illumination of the eye with a strong light concentrated by a lens, and intra-ocular causes of defective vision can be discovered by ophthalmoscopic examination. Detailed differential diagnosis of all the ocular causes of diminished vision requires a special knowledge of ophthalmology.

IV. COMPLETE BLINDNESS.

Total loss of vision, blindness, or amaurosis, may be: (1) *Bilateral*; (2) *Unilateral*.

Bilateral Blindness. Total blindness in both eyes may be congenital or acquired. Congenital blindness may be due either to absence of the eyes themselves, *congenital anophthalmos*, or to *congenital defects* in the development of the eyes. A large proportion of all cases of total blindness in the United Kingdom is due to *ophthalmia neonatorum*. Such cases as these can be recognized by the history of profuse inflammation or discharge shortly after birth, by the diffuse opacity on the surface of the cornea, associated, in some cases, with thinning and protrusion of the anterior part of the eye, and more or less nystagmus. There is a peculiar congenital malady known as *amaurotic familial idiocy*, in which several members of a family suffer from complete blindness owing to bilateral optic atrophy associated with idiocy due to slow development of the brain. The diagnosis is made from the family history and from the presence of optic atrophy dating from infancy.

Total blindness may also be caused by *bilateral inflammatory affections* of the eyes, such as iritis with blockage of the pupils and consequent glaucoma or ultimate shrinking

of the eyes, bilateral primary glaucoma, optic atrophy, or lesions of the optic chiasma. It is seldom due to lesions of the optic tracts, as this would only be caused by a bilateral lesion totally destroying the optic tract on both sides.

Total blindness of a *transient* nature may also occur in renal disease, and is termed *uræmic amaurosis*. This condition is recognized by its association with the symptoms of renal disease, whether in pregnancy or not, and by its sudden onset and short duration, the whole attack as a rule lasting not more than four or five days. In the majority of cases there is some evidence of renal retinitis, though in others the eyes are normal to the ophthalmoscope. The pupils usually react to light, though occasionally the light reflex is absent.

Another form of transient blindness occasionally met with is apparently due to *spasm of the retinal arteries* such as may result from *quinine*, though sometimes it seems to result from *arteriosclerosis*. In these cases the loss of vision may last only a few hours, and during its continuance it will be found that the retinal arteries are of a very slender calibre. It is to be noted that no cataract ever causes total blindness: provided that the rest of the eye is normal, a patient with the densest cataract can always perceive light, and also has the power of projection, or the recognition of the direction from which the ray of light is coming.

Unilateral Blindness. It is evident that unilateral blindness must be due to some lesion in the eye itself, or to one between the eye and the optic chiasma. Lesions of the optic tract above the chiasma do not cause monocular blindness, but **HEMIANOPSIA** (p. 377). Monocular blindness may be either sudden or gradual.

Gradual blindness may be due to any of the inflammatory affections of the eye mentioned above, or to such progressive diseases as optic atrophy or glaucoma.

Sudden blindness in one eye may be due to one of the following causes:

Detachment of the retina (*Fig. 427*, p. 520)
 Embolism of the central retinal artery
 (*Fig. 426*, p. 520)
 Thrombosis of the central retinal vein
 (*Fig. 422*, p. 519)
 Vitreous hemorrhage
 Acute glaucoma (*Fig. 428*, p. 520)

Injury to the optic nerve due to an accident
 or fracture of the base of the skull
 Compression of the optic nerve from hemorrhage or dilatation of the nasal sinuses
 Retrobulbar neuritis
 Migraine
 Hysteria.

The diagnosis of the majority of these causes is simple, owing to the characteristic ocular or ophthalmoscopic appearances. The only cases which present any obscurity are those in which there is sudden loss of vision without any visible ocular changes. These cases are usually due to retrobulbar neuritis, an acute affection of the optic nerve of obscure origin, characterized by rapid or even sudden loss of sight, with some pain and tenderness on movement of the eye. The loss of vision as a rule lasts for not more than twenty-four or thirty-six hours, and coincidently with the return of vision more or less definite neuritis appears at the optic disc (*Fig. 418*, p. 518). In the majority of cases vision returns entirely, but if there is a permanent defect it usually takes the form of a central scotoma.

Blindness due to compression of the optic nerve by *dilatation of the accessory nasal sinuses* can only be recognized after a thorough examination of the nasal passages: sinus disease of any duration is accompanied by well-defined appearances in the nose itself.

Monocular blindness may also occur in *migraine*, but in these cases it is of extremely short duration, seldom more than ten minutes or a quarter of an hour, and is followed by the characteristic headache, sickness, and fortification figures.

V. DEFECTS IN COLOUR VISION.

Defects in colour vision may be either congenital or acquired. In congenital colour blindness there is inability to recognize in the spectrum the six or seven definitely distinct colours which may be apparent to a normal eye. The commoner cases of colour blindness are those who can see only three colours in varying shades of black and white, or people who can distinguish only two colours, the spectrum being made up of yellow and blue, the one

gradually passing into the other. Red, orange, yellow, and green are seen as one colour, blue and violet as the other. Scarlet and grass-green appear very similar to these persons.

Cases of congenital colour blindness can be recognized by examination with coloured wools, as in Holmgren's test, or with much more precision and certainty in a dark room by means of a lantern with properly coloured glasses.

Acquired loss of colour vision may also occur in *tobacco* blindness or in *optic atrophy*.

Colour Defects.

Rainbow Vision.—Objects, especially lights, may be seen surrounded by a ring containing the colours of the spectrum. The causes of this are, as a rule, either *conjunctivitis* in which there is a thin film of mucus on the surface of the conjunctiva or *glaucoma*. The diagnosis in the two cases should present no difficulty, because the rainbow vision of glaucoma will be associated with the other important symptoms of this disease, viz., steaminess or lack of brilliancy in the cornea, a shallow anterior chamber, dilatation of the pupil, some limitation of the field of vision, especially on the nasal side, and increased tension in the eyeball.

Erythropsia, or red vision, occurs after prolonged exposure to white or violet light in conditions such as electric- or snow-blindness. It is accompanied by much inflammation and redness of the eyes, conjunctival discharge, and intolerance of light. It may also result from slight vitreous or retinal hemorrhages, though with severe vitreous hemorrhage vision is abolished entirely. Erythropsia, and in some cases blue vision, may occur after cataract extraction, and appears to be due to some fatigue of the retina.

Xanthopsia, or yellow vision, has been said to occur in jaundice, or in poisoning by *santonin*, *amyl nitrite*, *cannabis indica*, or *picric acid*, but it is hardly ever met with in practice.

Green vision (p. 335) has very occasionally been complained of by those susceptible to the toxic effects of *digitalis* administered for cardiac disease.

VI. ABNORMAL SENSATIONS OF SIZE.

Objects may appear rapidly to increase or diminish in size in the preliminary stages of an attack of epilepsy; and this variation in size of objects is a fairly common symptom in the slight delirium of infantile febrile disorders. *Micropsia*, or abnormal diminution in the size of objects, also occurs to many normal people during the act of reading. The book appears suddenly to recede to a great distance, and it and the type appear extremely minute, though absolutely clear. No satisfactory cause has yet been adduced for this phenomenon. It may be relieved by a momentary rest, and is of no pathological significance. A similar condition may be produced by the use of certain drugs, particularly *cannabis indica* and its products; and it is sometimes attributed to that ill-defined state of affairs known as 'biliousness'.

VII. DAY-BLINDNESS AND NIGHT-BLINDNESS.

Day-blindness, or *hemeralopia*, is caused most commonly by *tobacco poisoning*, it being probable that this condition is due to a direct poisoning of the retinal cones, which are endowed with the faculty of effective vision in lights of high brilliancy. In *snow-blindness*, also, vision improves directly the light begins to fail, and defective vision in bright light is a common symptom of *albinism*. Except in the case of albinos, the retina may show no abnormal signs.

Night-blindness, or *nyctalopia*, occurs most frequently in *retinitis pigmentosa*, diagnosable at once on ophthalmoscopic examination by reason of the small ill-defined optic disc, thin thready arteries and veins, and the characteristic spider-like pigment cells seen at the periphery of the fundus. It also occurs in cases of *quinine amblyopia*, *xerosis of the conjunctiva*, *disseminate choroido-retinitis*, and it used to be one of the marked phenomena in sailors suffering from *scurvy*. Patients suffering from *high myopia* may also suffer from defective vision in dim lights.

Herbert L. Eason.

VISION, DOUBLE. (See DIPLOPIA, p. 220.)

VISION, GREEN.—(See GREEN VISION, p. 335.)

VOICE, ABNORMALITIES OF THE. (See SPEECH, ABNORMALITIES OF, p. 769.)

VOMITING. Strictly speaking, the term vomiting implies the return and expulsion from the mouth of part or the whole of the stomach contents. There are several conditions in which vomiting may be simulated closely, although the vomited matter has never reached the stomach. It will be convenient to deal with these before discussing the causes and differential diagnosis of true vomiting or gastric regurgitation.

In certain *diseases of the œsophagus* food may be swallowed and, after a varying interval of time, brought up again. These conditions are :

Malignant disease
Fibrous stricture
Spasm

Pressure from without, as by aneurysm,
new growth
'Idiopathic' dilatation
Diverticula 'pressure' pouches.

If the obstruction be of long standing, and near the lower end of the œsophagus, the interval between taking food and its regurgitation may be prolonged considerably, especially in cases in which the lumen has undergone much dilatation. This may occur with fibrous stricture, slow-growing carcinoma, or the rarer cases known as 'idiopathic' dilatation of the œsophagus or achalasia.

A 'pressure' pouch produced by a hernia-like protrusion of the mucous membrane through the muscular coats of the upper part of the œsophagus becomes filled gradually, and, in addition to dysphagia caused by the pressure it exerts on the œsophagus below, may simulate vomiting when its contents are voided.

The differential diagnosis of these œsophageal causes of vomiting, or rather regurgitation, is usually easy. The returned matter is practically unaltered, and is undigested. It may be diluted freely with mucus. Blood may be present, and even portions of growth in cases of carcinoma. In œsophageal pouches food may be retained for long periods and returned unchanged. The most important point to recognize is that in such œsophageal conditions the returned matter is alkaline or neutral in reaction. The diagnosis is confirmed by examination with a bougie, or by the X rays after administration of bismuth emulsion (*Figs.* 203-208, pp. 241-244).

Certain individuals may acquire the power of voluntarily regurgitating portions of the stomach contents into the mouth, which may be ejected or again swallowed. There is no accompanying nausea. This condition, known as 'rumination' or 'MERYCISM' (p. 485), must be distinguished from vomiting.

Mention must also be made of conditions in which the mechanism of deglutition is deranged, and in which swallowing is interfered with to such an extent that the food or drink is returned. This may occur in cases of bulbar paralysis, myasthenia gravis, etc. Again, in diphtheritic paralysis the return of fluids through the nose, owing to the paralysis of the soft palate, may be mistaken for vomiting. A similar mistake may occur in cases of bronchiectasis in which, during the act of coughing, quantities of pus have gushed up, not only from the mouth but also through the nose.

The regurgitation of milk in healthy breast- or bottle-fed infants after a hearty meal is frequent, and is often wrongly regarded as vomiting. It is due to simple overfilling, or sometimes to too rapid feeding : air that has been swallowed is belched up, and drives out some of the milk with it.

A brief account of the *mechanism of vomiting* will facilitate a classification of its causes. The parts concerned are the muscular coats of the stomach : the sphincter at the cardiac orifice : the diaphragm and the abdominal muscles : the vomiting centre situated in the medulla : the efferent nerve fibres in the vagus supplying the musculature of the stomach, the phrenics the diaphragm, and the spinal nerves the abdominal muscles.

In the act of vomiting the walls of the stomach contract, the diaphragm is pushed violently downwards in full inspiratory position, while powerful contractions of the abdominal muscles take place : at the same time the cardiac sphincter is relaxed, and the gastric contents are expelled, chiefly as the result of the pressure exerted on the stomach by the diaphragm and the abdominal muscles, aided to some extent by reversed peristalsis. The pyloric sphincter is usually closed, but it may become relaxed, in which case bile and intestinal contents may enter the stomach and be found in the vomit. The vomiting

centre may be excited to action by stimuli reaching it from the stomach itself, by afferent fibres in the vagus, or from other parts by many different afferent channels. The centre may also be thrown into action by toxic substances acting on it directly, for instance as the result of a subcutaneous injection of apomorphine.

In *retching* forcible contraction of the stomach wall and of the diaphragm and abdominal muscles takes place as in vomiting, but there is no relaxation of the sphincter. In the condition known as *waterbrash* or *pyrosis* (see HEARTEURS, p. 376), in which a quantity of clear fluid is brought up into the mouth, usually on rising in the morning, the complete act of vomiting does not occur; relaxation of the cardiac sphincter takes place in association with powerful reflux peristalsis of the stomach walls but without attendant muscular contraction of the diaphragm and the abdominal muscles.

It is obvious from the above that the causes of vomiting must fall into two great groups: (I) *Those acting directly on the vomiting centre*, such as certain poisons, e.g., apomorphine; (II) *Those acting reflexly on the centre*. The second group is a very large one, as it includes practically all the pathological states of the stomach, many visceral diseases, and disturbances of special senses.

I. CENTRAL CAUSES.

Certain drugs such as apomorphine	Diabetes	Onset of acute infections especially in children
Tobacco	Acute yellow atrophy of the liver	Pregnancy
Anæsthetics	Addison's disease	Recurrent, periodic, or cyclical vomiting in children.
Uræmia		

There may be some doubt as to whether Addison's disease, pregnancy, and recurrent vomiting should be included in this group, as their pathology is not fully known. The vomiting of pregnancy may be partly reflex, but there is evidence that a toxic element exists, and is probably the chief exciting cause. The differential diagnosis of these conditions presents little difficulty. The examination of the urine will give evidence of the existence of renal disease in uræmic vomiting, and the onset of drowsiness and coma in a diabetic patient may be attended by vomiting. Persistent vomiting occurring in a case of jaundice of apparently the common catarrhal variety should arouse suspicion of its proving acute yellow atrophy. The size of the liver should be determined carefully, and any diminution noted; the urine should be examined for leucin and tyrosin (*Fig.* 326, p. 416). Vomiting associated with asthenia, characteristic pigmentation of skin and buccal mucosa (*Figs.* 500-502, p. 641), and a persistent low blood-pressure, would be diagnostic of Addison's disease. The form of vomiting met with in young children, termed 'periodic', or 'cyclical', is very severe, and is accompanied by great wasting. The symptoms pass off after a few days, but tend to recur at intervals of months. The urine during the attacks often contains acetone and diacetic acid, and the condition may be regarded as an auto-intoxication, probably an acidosis (see ACIDOSIS, p. 3). The vomiting met with as one of the earliest symptoms in specific fevers, especially in children, is chiefly due to the direct action of the specific toxin on the cerebral centre, though reflex action may also have a share in it; the diagnosis does not usually present difficulty: the acute onset, vomiting, general malaise, headache, pyrexia, sore throat, rash, etc., give the clue to the cause of the vomiting. In older patients scarlet fever is the commonest specific fever to begin with nausea and vomiting.

We must next consider the chief characteristics of the vomiting due to reflex causes.

II. REFLEX VOMITING.

1. Gastric Causes.—

Irritating articles of food (hard, indigestible substances)	Gastritis:	Dilatation and 'hour-glass' contraction
Emetics, such as zinc sulphate, mustard, etc.	Acute: (a) Simple; (b) Phlegmonous	Malignant disease
Poisons:	Chronic	Ulcer
Corrosives, irritants	Pyloric obstruction:	Venous congestion, as in morbus cordis, portal obstruction, cirrhosis of the liver
	Malignant disease	
	Fibrous stricture	
	'Hypertrophic stenosis' in infants	
	Pressure from without	

2. **Intestinal, Peritoneal, and General Visceral Causes.**—

Intestinal obstruction	Acute pancreatitis	Irritation of the fauces or
Appendicitis	Certain conditions of the female genital organs :	bronchi by direct stimulation, or by severe coughing :
Intestinal worms	Pregnancy	Pertussis
Following administration of enemata	Retroversion of the uterus	Bronchiectasis
Henoch's purpura	Ovarian disease	Fibroid lung
Peritonitis	Extra-uterine gestation	Shock :
Biliary colic	Phthisis vomiting may be of	Blows on the epigastrium,
Renal colic; movable kidney (Diehl's crises)	central origin or due to irritation of the bronchi	injury of testicle, a kick on the internal semilunar cartilage of the knee, etc.

3. **Affections of the Central Nervous System.***Special Senses :*

Offensive smells, tastes, repulsive sights.

Brain :

Concussion	Cerebral haemorrhage	Epilepsy
Cerebral tumour or abscess	Thrombosis of cerebral sinuses	Sea, train, or motor-car sickness
Meningitis	Middle-ear disease; Menière's disease	Functional or hysterical vomiting.
Hydrocephaly	Migraine	

Spinal Cord :

Tabes dorsalis, gastric crises.

Certain general principles may be laid down as important in the diagnosis of the cause of vomiting. Attention should be paid to its relation to food, if any, and at what interval after a meal it occurs; whether preceded or not by pain; whether attended or not by nausea. The absence of nausea is a point of great significance; nausea is usually present in vomiting due to abnormal states of the alimentary tract or viscera, but is often absent in that due to concussion, cerebral tumour, meningitis, or other disease of the brain.

The vomited matter should be inspected carefully, and its quantity and general character noted. Alcohol, and certain poisons such as carbolic acid and prussic acid, may be recognized by their *smell*, or a faecal odour may be distinguished. *Blood* may be present, either dark or bright red, or dark brown and resembling coffee-grounds. Slight streaks of blood are common with severe vomiting, and are usually due to rupture of small vessels in the oesophagus or pharynx. In whooping-cough blood is often mixed with mucus from the respiratory passages, and the contents of the stomach are ejected during the paroxysms. The *condition of the food remains* should be noted: the presence of substances, such as currants or seeds, taken it may be many hours or a day previously, would point to motor insufficiency of the stomach, either with or without pyloric obstruction; shreds of meat returned unaltered some hours after a meal indicate deficient protein digestion.

The *reaction* should be ascertained: in corrosive poisoning this may be strongly acid or alkaline according to the toxic agent. It need hardly be said that in any case of suspected poisoning the vomit should be kept for analysis. *Microscopical examination* may show sarcinae (Fig. 258, p. 302), yeast cells, the Oppler-Boas bacillus, or cell elements from a malignant growth. Intestinal contents may be mixed with the vomit. *Bile* is often present in severe or protracted vomiting, and is recognized readily by its colour and the usual tests. *Faecal matter*, when present, is recognized by the characteristic odour and the brownish coloration it imparts to the vomit: it usually occurs as the result of intestinal obstruction. Gastrocolic fistula may give rise to faecal vomiting.

1. Gastric Causes. Most *corrosive and irritant poisons* cause vomiting immediately after swallowing, accompanied by intense burning pain in the epigastrium. The vomit contains food, blood, mucus, and may have the characteristic odour of the poison. With some irritant poisons, e.g., arsenic or phosphorus, the vomiting may come on later and resemble that of an acute gastritis. The diagnosis will depend largely on the chemical analysis of the vomit, and the associated signs and symptoms. Recognizable shreds of the gastric mucosa may be seen, or even a large area of the mucosa forming a partial or complete cast of the interior of the stomach.

In *acute gastritis* there is repeated vomiting, usually very severe, and attended by

nausea and abdominal pain. Vomiting occurs shortly after taking food, and causes some relief of pain. The vomited matter consists at first of food ingested, later of mucus and bile. There are often accompanying diarrhoea and febrile disturbances, especially in children. In the *phlegmonous* form the constitutional symptoms are exceedingly grave; pus is rarely found in the vomit, bile is often present.

In *chronic gastritis* the vomiting is associated with nausea and epigastric pain. There is usually much flatulence. The vomited matter consists of partially digested food, mucus, and a considerable quantity of sour-smelling fluid. Hydrochloric acid is usually reduced greatly in amount, or may be absent. When *dilatation* of the stomach is present the quantity of fluid ejected is often very large: portions of food taken many hours previously may be returned. Fermentation takes place in the stagnant gastric contents, so that the vomit, when collected in a glass vessel, often shows an uppermost layer of brown froth, a middle greenish-grey layer of fluid containing streaks of mucus, and below this a semi-solid deposit containing food remains, sarcine (*Fig. 258*, p. 302), yeast cells, and bacteria: chemical tests show the presence of lactic acid and a diminution or absence of free or active hydrochloric acid.

'Hour-glass' contraction, due to transverse constriction of the stomach by fibrous tissue, may be a cause of vomiting which resembles in most respects that associated with dilatation. Examination with the X rays after a barium meal will generally establish the diagnosis (*Fig. 275*, p. 339).

The vomiting due to *pyloric obstruction* in adults presents no characteristics other than those associated with the dilatation of the stomach which usually results from it: finding with the X rays that there is a large residuum of barium in the stomach eight hours after the intake of an opaque meal affords the most direct method of demonstrating pyloric stenosis. The absence of free hydrochloric acid in the vomit would favour the diagnosis of carcinoma, the presence of free hydrochloric acid that of fibrous stricture: the presence of the Oppler-Boas bacillus is regarded by many as diagnostic of carcinoma. Persistent vomiting in young infants, especially if breast-fed, attended with wasting and constipation, should always arouse suspicions of the existence of *hypertrophic stenosis of the pylorus*. The vomiting in these cases is very forcible, the milk being pumped up violently, often very shortly after a feed, and little altered. Visible gastric peristalsis and the presence of a small tumour in the epigastrium would complete the diagnosis.

Vomiting due to *gastric ulcer* (non-malignant) is very common. Pain occurs soon after taking food, and is relieved by vomiting, which usually occurs within an hour. The vomit consists of food, more or less digested, according to the time which has elapsed after a meal. It almost always contains at least the normal quantity of free hydrochloric acid, and blood may be present in varying quantity.

With *malignant disease* carcinoma of the stomach though the general character of the vomit may be similar to that in simple ulcer, there is usually a great diminution or complete absence of free hydrochloric acid, and lactic acid and the Oppler-Boas bacillus are often present. Sarcine may be present also when there is accompanying dilatation. Occasionally portions of the growth may be found in the vomited matter. In both simple and malignant ulcer blood may be detected in the vomit microscopically or spectroscopically (see BLOOD PER ANUM, p. 104) when it is not recognizable by the naked eye. A bismuth and X-ray examination is almost essential (*Figs. 277, 278*, p. 340; *Figs. 279, 280*, p. 341; *Fig. 281*, p. 342).

2. Intestinal, Peritoneal, and General Visceral Causes. In *intestinal obstruction* vomiting sets in after an interval the length of which may depend on the situation of the blocking. The vomiting is severe and persistent: the contents of the stomach are returned first, and later, mucus, bile, and intestinal contents, often of a dull brown colour and thin fluid consistence: obvious pieces of faecal matter are rarely distinguishable. Faecal vomiting should be recognized at once by its odour. The vomiting occurs the earlier and is the more severe the higher the obstruction is situated in the intestinal canal.

Vomiting is commonly present in *appendicitis*, but in slight cases does not persist after the onset. In the severe forms of the disease the vomiting may be a prominent symptom, and resemble that met with in intestinal obstruction: it is sometimes faecal.

Intestinal worms are a cause of vomiting in children, probably owing to the reflex irritation they set up. Occasionally a round worm is found in the vomit.

Enemata in certain individuals cause vomiting, and rare cases have been described in which the fluid injected per rectum has been returned by the mouth.

Vomiting is a common symptom in the condition known as *Henoch's purpura*, and may be due to either gastric or intestinal stimulation. The vomit may contain blood due to hemorrhages from the mucous membrane of the stomach. It is usually accompanied by abdominal pain, sometimes of an acute and agonizing character closely simulating that occurring with intestinal obstruction, these symptoms being due to hemorrhage into the intestinal wall or the mesentery, which occasionally simulate or even give rise to intussusception. Recurrent attacks of vomiting and abdominal pain associated with a purpuric eruption in a boy or girl would point to the existence of this not uncommon disease.

In *acute peritonitis* vomiting is an early symptom, and causes great pain: rarely the vomit may have a faecal odour. The history, together with the rigidity and immobility of the abdominal wall, generally indicates the need for early laparotomy.

In *biliary* and *renal colic* the vomiting accompanying the attacks of agonizing pain presents no special features. The pain in the upper right part of the abdomen, and the onset of jaundice, distinguish biliary colic from that due to renal calculus, in which the pain is in the loin or the lower abdomen, shooting down towards the groin and testicle. Jaundice is absent if the stone is in the cystic duct.

Acute pancreatitis may simulate intestinal obstruction closely in that it is attended by nausea and vomiting, constipation, and severe abdominal pain. The vomit is not faecal in character: there is usually localized tenderness over the pancreas. The diagnosis is seldom made, however, until laparotomy is performed on account of the urgency of the symptoms, when typical fat necrosis (*Fig.* 625, p. 810) will be found in the omentum.

3. Affections of the Central Nervous System. It has been pointed out that in most of the preceding conditions nausea accompanies vomiting, and this brings us to a most important distinction, namely, that in intracranial disease a special type of vomiting is met with, generally known as 'cerebral vomiting'. In this, nausea is absent, vomiting occurs suddenly and often without warning, and bears no relation to the ingestion of food. The whole or part of the stomach contents are returned. Vomiting of this type, especially if accompanied by headache or by optic neuritis, should arouse grave suspicion of the existence of organic cerebral disease—such as tumour, abscess, meningitis, or sinus thrombosis. 'Cerebral vomiting' may also occur in hydrocephaly due to increased intracranial pressure. Optic neuritis (*Figs.* 418, 419, p. 518) should be looked for in all cases of vomiting associated with headache.

Cerebral hemorrhage may be attended by vomiting, more often when the cerebellum is the part affected than when other parts of the brain are involved.

In *Mènière's disease* vomiting may follow the attack of vertigo. Nausea and vomiting frequently accompany the severe headache associated with attacks of *migraine*.

Functional or hysterical vomiting is not attended by nausea or pain: portions of a meal are brought up, usually fluids: and although the vomiting may be a frequent occurrence the general state of nutrition often remains good. Other hysterical manifestations are generally present in these patients. Cases have been recorded in which the vomit contained faecal matter.

The *gastric crises* in tabes are attacks of vomiting accompanied by severe epigastric pain. The attacks usually last for several days, and tend to recur at intervals of weeks. Nausea may be absent. During the intervals digestion may be carried on normally. The diagnosis depends on the presence of the characteristic Argyll Robertson pupil and the loss of the knee-jerks.

The influence of *anæmia* upon vomiting, and the manner in which gastric ulcer may be simulated thereby, have been discussed in the article on *ANÆMIA* (p. 48).

WATERBRASH. (See *HEARTBURN*, p. 376.)

WEIGHT, LOSS OF.—Loss of weight sooner or later accompanies all cases of cancer, phthisis, starvation from lack of food or from inability to swallow, and similar conditions ; but in most such cases there are other symptoms pointing to the diagnosis. The present article is concerned chiefly with those cases in which, without other definite symptoms, the patient has been losing weight.

In the case of children, the commonest causes are malnutrition from injudicious feeding, the eating of sweets between meals, gastro-intestinal infections, and latent tuberculosis (see MARASMUS, p. 479).

If the patient is an adult and the loss of weight has been considerable, the first suspicion will almost certainly be that there is either *phthisis pulmonalis*, *deep-seated* or *latent carcinoma* or *sarcoma*, *tuberculosis* other than pulmonary, or *diabetes mellitus*. All the systems, including the urine, the rectum, and, if need be, the vagina, will need careful routine examination.

Tuberculosis.—Any sputum that may be obtainable should be examined for tubercle bacilli ; the physical signs at the apices of the lungs should be watched with extreme care, particularly if there is any difference in the amount of subcutaneous fat on the two sides in this region : the X rays may be of value in detecting mottling (*Figs. 117-119*, pp. 133-135) at one or other apex when the mischief is too far from the surface to give abnormal physical signs to percussion or auscultation. Those who believe that the opsonic index to tubercle bacilli is of diagnostic significance would estimate it before and after inoculations with small or moderate doses of tuberculin : the family history might be of assistance in indicating the likelihood of a lung lesion, whilst the personal history as to the drinking of much unsterilized milk would indicate the possibility of infection by so-called surgical tuberculosis in the lymphatic glands, abdomen, a joint, or the spinal column ; von Pirquet's skin reaction to tuberculin may be tested. The test is performed upon the skin by a procedure analogous to that of ordinary vaccination, but using tuberculin in place of calf lymph ; the degree of positivity of the von Pirquet test is ascertained by using 5, 10, 15, 20, and 25 per cent strengths of tuberculin, supplied ready for the purpose by bacteriological laboratories ; any reaction shows itself within twenty-four hours. A negative von Pirquet's reaction is of more value in excluding tuberculosis, however, than is a positive one in proving that the patient's symptoms are due to tubercle ; so many persons have latent tuberculous foci in glands or elsewhere that they may give a positive tuberculin reaction though their actual symptoms may be due to some entirely different malady—a coli bacilluria, for instance, or something else that is non-tuberculous. A positive von Pirquet reaction shows that the patient is the subject of tubercle, but it does not prove that the symptoms one is investigating are due to the tuberculous infection so discovered.

Another method of using tuberculin for diagnostic purposes is by subcutaneous injection ; at one time this was regarded as dangerous, but experience has shown it to be free from danger and quite valuable. The difficulty is to obtain a supply of Koch's Old Tuberculin, which in the necessary dilution is neither inert, as much of it is, nor excessively active ; each brew needs testing clinically before its reliability one way or the other can be ascertained, and it is this which limits its use in practice. One cannot rely on any chance supply from a commercial source. If, however, a reliable brew is to hand, it may be employed in a dilution of 1-1000 in normal saline, doses of 0.5 c.c., 1 c.c., and 2 c.c. being employed. Each dose is given subcutaneously with a hypodermic needle and syringe ; there should be four day's interval between one dose and the next ; and as a rule, if the case is tuberculous, a positive reaction is given by either the 0.5-c.c. dose or by the 1-c.c. dose without the 2-c.c. dose being required. The diluted tuberculin will not keep good in glass bulbs. A positive reaction is indicated mainly by two things : (1) The local reaction at the site of injection, around which the skin becomes swollen, reddened, and tender, over an area two or three inches in diameter, the reddening coming on within twenty-four hours and lasting two or three days ; and (2) The temperature chart, in which after a well-defined latent period of about twelve hours there is a decided rise, followed by a more gradual fall during the succeeding twenty-four hours. It is best if the temperatures are recorded two-hourly. The chart-reaction is only available in apyrexial cases, but it is characteristic in these ; the charts on p. 360 (*Figs. 295, 296*) show a positive and a negative response in two cases which were clinically similar ; the positive one developed later into phthisis, the negative proved to be simple bronchial catarrh.

Sometimes, when there is doubt as to whether there is organic disease or not, the nails afford a clue : whereas longitudinal ridges on them matter little, a definite transverse ridge or a band of pallor at the same level across all the nails is evidence of dystrophy due to illness at a time corresponding to that at which the ridged or pallid part was being produced from the matrix : roughly speaking it takes a nail between four and six months to grow from matrix to tip, and of this time about two-thirds applies to the visible nail, one-third to the part that is growing but not yet visible ; if, therefore, there is a definite transverse ridge on all the nails (*Fig. 387*, p. 497) about half-way along each, the patient was in bad health between three and four months previously. There may have been a definite acute illness such as pneumonia ; but quite frequently the dystrophy is due to less definite illness, and particularly to the effects of developing phthisis.

Notwithstanding the most careful investigations, however, doubt as to the cause of the loss of weight in not a few cases remains until, in the course of time, the patient either recovers the lost ground and gets quite well, or else develops other signs or symptoms of growth, tuberculosis, or other definite disease.

Young persons may lose weight as the result of change of surroundings, for instance from active out-door school life to work in a city office : care and anxiety : the undertaking of serious responsibilities : sorrow : love : too strenuous a life of pleasure : irregularity of meals : too long hours of work : these are amongst the everyday causes of what at the time may appear to be serious loss of weight.

Any affection of the alimentary tract interfering with proper digestion and absorption of food may produce loss of weight, especially if there is cause for sapremia at the same time ; one may mention in this connection loss of appetite from too much smoking, excessive drinking, monotony of food or of existence, carious teeth, ill-fitting tooth plates, pyorrhea alveolaris, dyspepsia, flatulence, the abuse of purgatives and the constipation which results therefrom : gastric or duodenal ulcer : colitis in its many forms. The wasting is seldom severe in any of these : but when gastric symptoms are prominent for instance, it may be very difficult, for the time being, to tell whether the mischief should be labelled merely dyspepsia or actual carcinoma ventriculi. Analyses of the gastric juice were at one time thought to be valuable in deciding between simple and malignant affections of the stomach, but this is by no means always so (p. 341). X-ray examination after a bismuth meal may be more helpful. If, under observation and treatment, the patient succeeds in gaining weight, or even ceases from losing more over a period of some weeks, the argument is against carcinoma : but if doubt remains, and surgical measures are to be adopted before carcinoma has passed the stage of curability, it will often be wise not to postpone laparotomy too long as a means of settling the diagnosis. It is too late if one waits until there is a tumour.

Any malady which produces *sleeplessness* or *pain*, or both, may lead to serious loss of weight, and thus to difficulty in the diagnosis. A thoracic aneurysm, for instance, may erode the vertebrae and produce severe intrathoracic pain which in turn produces insomnia, and may thus cause so much loss of weight that neoplasm may be suspected.

Chronic microbial infections may not be obvious in themselves, and yet they may produce loss of weight by interfering with the general nutrition : one sees this in many persons who have returned from the tropics after infection there by dysentery, yellow fever, malaria, dengue, and so forth. At home, chronic infections of the joints, the skin, the alimentary tract, the uterus, and genital organs may produce loss of weight in a similar way. One would mention in particular coli bacilluria (see BACTERIURIA, p. 88), a common malady, the diagnosis of which is possible only on bacteriological examination of the urine, though it may be suggested by the discovery in the latter of a trace of albumin and, on microscopical examination, excess of leucocytes.

Liver affections exert a prominent influence upon general nutrition, and the loss of weight exhibited by some sufferers from cirrhosis is familiar, though in the early stages the patient may be fat, and towards the end loss of weight may be masked by a false increase due to ascites. Pernicious anæmia is diagnosable with certainty only by blood examination (see ANÆMIA, p. 30), though it may be suggested by the primrose-yellow colour of the skin ; but one marked feature of the malady is that, although the patient does not at first decrease much in bulk, the tissues, from conversion into or

replacement by fat, become of less specific gravity than normal, so that they diminish materially in weight.

The effect of *alcohol* upon body weight is variable, some persons becoming exceedingly stout, others not changing much, and others becoming extremely thin. Broadly speaking it is spirit drinkers who decrease in weight, and in some cases serious doubts may arise as to whether the loss in such a patient is due to alcoholic habits only, or whether there is not some new growth or tuberculous affection as well. When alcoholism leads to peripheral neuritis there is rapid and extreme loss of weight as the result of the muscular atrophy, and the same applies to other conditions of multiple peripheral neuritis (p. 82).

Certain drugs have the power, especially in certain individuals, of reducing weight materially, even though the diet remain the same: the best known of these is *thyroid extract*, whilst a long way second comes *fucus vesiculosus*. It will seldom happen that either of these is being taken accidentally, so that the diagnosis of loss of weight due to them is generally obvious.

It is very difficult sometimes to be sure whether the loss of weight that may be complained of in a patient of sixty or seventy years of age is due merely to *old age*, or whether it is due to underlying growth or senile phthisis.

Diabetes, especially diabetes mellitus in young subjects, may have loss of weight for its earliest and most prominent symptom: but the diagnosis is easy when the urine has been examined.

Addison's disease is another affection in which, besides the progressive asthenia, loss of weight, though not essential, is sometimes marked. There may or may not have been syncopal or gastric attacks: the diagnosis depends almost entirely upon the discovery of abnormal pigment deposits in the form of patches or spots, not only upon the skin of the neck, limbs, and trunk, but also beneath the mucous membranes, particularly of the mouth (*Figs. 500-502*, p. 641), where they are generally best seen inside the lips, or within the cheeks. The blood-pressure is sometimes very low in these cases, and if, on actual measurement, it is found to be 70 or 80 mm. Hg, this fact tends to confirm the diagnosis.

Just as the administration of thyroid extract diminishes weight, so may loss of weight be a prominent feature in cases of *Graves' disease*: sometimes, indeed, it may be the first symptom to attract attention, especially in those cases in which there is no exophthalmos. Tachycardia, nervousness, fine tremor of the outstretched fingers, and symmetrical but not extreme enlargement of the thyroid gland, would confirm the diagnosis.

Anorexia nervosa is a disease in which wasting from disinclination to eat any kind of food except in the smallest quantities is the most prominent symptom: the patient is nearly always a female, between the ages of fifteen and twenty-five: there may or may not be other evidence of functional nerve disorder. The patient, perfectly robust until puberty or shortly afterwards, begins to lose all appetite, the body wastes, and the weight

comes even to so little as four or three and a half stone. One sometimes sees girls of 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

Herbert French.

WHEELS, the characteristic lesion of *urticaria*, may be defined as flat, evanescent elevations of the skin, the result of an oedema of the dermis. They are the expression of an angioneurotic excitation, internal or external, which causes a dilatation of the vessels that permits an exudation of plasma. Wheals disappear rapidly as a rule without leaving any trace. They are usually pale in the centre, with a red periphery: but they may be uniformly rose-red, or may have a whitish periphery: or, as the result of hemorrhage

into them, they may be purplish. In size they vary from a pin-head upwards. The smaller ones may take the form of conical or acuminate papules, frequently surmounted by a tiny vesicle, especially in infants with tender skin. As a rule they are flat or very slightly raised : but the larger ones, when not the result of coalescence, are hemispherical. They may also be linear, several inches in length, and by running together they may form roughly circular plaques. They usually appear suddenly, last individually only a few hours, but may be succeeded by others in adjacent parts. They are always accompanied by itching or burning, which may be intense. The commonest causes are dietetic : some persons are more susceptible than others, but the kinds of food most likely to cause the symptoms are fried fish, crab, lobster, mussels, and other shell-fish : strawberries constantly produce an attack in certain individuals.

It is not necessary to give a detailed description of the different forms of urticaria : the only other affection in which wheals appear is urticaria papulosa (lichen urticatus), the differential diagnosis of which has been given elsewhere. The sudden onset, the presence of the wheals, the usually fugitive character of the eruption, the irregular distribution, and the severe itching, make up a clinical picture which is generally unmistakable. In *bullous urticaria*, however, in which the wheal is crowned or is replaced by a bleb, the affection may be confused with pemphigus or with the erythematous stage of dermatitis herpetiformis : but its true nature is indicated by the history of the case, the course of the eruption, and the almost invariable presence at some points of typical lesions. In cases in which the constitutional symptoms are pronounced, the rash may be mistaken at first for that of scarlet fever, or even for erysipelas : but the course of the lesions will quickly correct the error.

When wheals are due to such local and accidental causes as the *bites of insects*, or contact with the *stinging-nettle*, the diagnosis is furnished by the history, and in insect bites by the central punctum : when due to drugs, knowledge of what the patient has been taking is the basis of the diagnosis : the commoner remedies that may produce urticarial wheals are antipyrin, sulphonal, veronal, aspirin, salicylates, iodides, bromides, morphia, antimony, quinine, santonin, copaiba, salvarsan and its allies : and various normal or antitoxic sera—the urticarial eruption from serum injections appearing usually about eight days after the dose has been given subcutaneously : severe urticaria may follow human blood transfusions when the blood given has not been fully compatible with the patient's.

Some skins are so sensitive even in apparent health that wheals rise upon the surface in response to mechanical excitation : for instance, one may be able to write with the finger-nail upon the skin, the latter soon afterwards rising into wheal-like elevations corresponding to the markings made : one may write a patient's name upon his back in this way—dermatographia (*Fig. 654*, p. 856)—and yet the condition is but an idiosyncrasy, not a disease or an indication of disease.

X-RAY DIAGNOSIS BY SPECIAL METHODS. The use of skiagraphy in diagnosis is dealt with in many parts of this volume : and the index contains references to the results obtained from ordinary radiograms connected with the bones, the lungs, the heart, the mediastinum, foreign bodies, and calculi in various places. The results of barium or bismuth meals followed by X rays, and of radiography after bismuth or barium enemata, are referred to in many of the articles : pycelography is discussed on pp. 445 et seq. : and the use of X rays after injecting lipiodol into the spinal canal when locating the site of spinal-cord compression is illustrated on p. 326.

There are other and special methods of employing X rays in diagnosis, however ; and some of these merit mention :—

Skiagraphy of Organs after Injection of Oxygen around them. It is particularly in defining the kidney that this method has been employed ; the technique is special, but when it is desired to produce a more than ordinarily clear picture of a kidney the latter may be seen much more brightly when a skiagram is taken after the perinephric tissues have been infiltrated with oxygen through a suitable hollow needle than when the organ is radiographed in the usual way. The procedure is, however, associated with a greater degree of discomfort to the patient than is justified, as a rule, so that it is employed only exceptionally.

Skiagraphy after Distention of the Lateral Ventricles of the Brain with Oxygen or Air.—The technique by which oxygen or air is introduced into the lateral ventricles of the brain is surgical ; it is not a dangerous procedure, however, and the injected air, diminishing in quantity daily, becomes absorbed completely in a little over a week. Skiagraphy can be carried out at relative leisure after the injection ; and in difficult cases the information

Fig. 687.—Skiagram showing a normal lateral ventricle of the brain after its distention with oxygen. (Lateral view.)
(By Dr. J. H. Mather.)

obtained may be of value, not only in diagnosis, but also sometimes in guiding the surgeon as to which side of the head to operate on. The normal appearance of a lateral ventricle distended in this way is shown in *Fig. 687* ; enormous distention of the lateral ventricles such as occurs in hydrocephalus is illustrated in *Figs. 688* and *689* ; intermediate degrees are found in connection with cerebral tumour, after meningitis, or with abscess ; very occasionally deformity of the air shadow serves to depict the outline of a tumour itself when it is bulging into a lateral ventricle.

Skiagraphy of the Bronchial Tubes after Injection of Lipiodol into them. The technique by which the condition of the bronchial tubes may be made visible by means of X rays after injecting lipiodol through the trachea into the bronchial tree is in its infancy ; but already great strides have been made in this direction, and, in cases selected as suitable, it is a method of investigation that seems likely to develop much further. Bronchiectatic cavities may be demonstrated in this way (*Fig. 690*) ; occasionally the lipiodol may be made to enter a buried empyema that has opened into a bronchus ; and, although it is less easy to cause the lipiodol to enter apical cavities than it is those nearer the base, the

method may be valuable in demonstrating cavities in the lung in phthisis. The difficulty is to be quite certain that the spaces one desires to fill are not already so filled

Fig. 630. —Skiagram of bronchiectatic cavities after intratracheal injection of lipiodol. There is also a small amount of fluid in the pleural cavity at the right base. (By Dr. J. H. Mather.)

with purulent secretion that entry of the lipiodol is prevented; absence of abnormal shadows after the injection cannot be taken as proof that there are no abnormal holes in the lung.

Skiagraphy of the Uterus and the Fallopian Tubes after Intra-uterine Injection of Lipiodol. It is sometimes important to determine whether the Fallopian tubes are patent

Fig. 691. Skiagram of the uterus and Fallopian tubes after intra-uterine injection of lipiodol. The left tube is patent; the right tube is stenosed. (By Dr. R. E. Roberts.)

or occluded: this is possible in certain cases if X rays are employed after intra-uterine injection of lipiodol. The latter passes readily through a normal Fallopian tube, and the

results obtained with blocked and with patent tubes are exemplified by *Figs. 691 and 692*. The shape of the interior of the uterus can be determined at the same time ; and this may

Fig. 692.—Skiagram of the uterus and Fallopian tubes after intra-uterine injection of lipiodol. A few droplets of the latter have passed through the ostium of the patent right tube into the peritoneal cavity ; the left tube is closed. (*Re Dr. R. E. Roberts.*)

be important in connection with such conditions as carcinoma of the body of the uterus, intra-uterine polypus, or a fibroid of the uterus bulging into one side of the lumen.

Skiagraphy of the Gall-bladder after the Administration of Sodium Tetraiodophenolphthalein or Sodium Tetrabromophenolphthalein. The technique is the same whether the iodo- or the bromo-preparation is employed; and most observers use the iodo-salt. Given by the mouth, or intravenously, the dye is excreted by the liver in the bile, and possibly also by the walls of the gall-bladder, with the result that the gall-bladder and its contents, otherwise invisible with the X rays, become defined clearly as a dark shadow, unless the cystic duct is occluded, as in the case of a simple mucocele of the gall-bladder, or of a gall-stone impacted in the cystic duct, or of a carcinoma of the cystic duct, or of new growth stenosing this duct from the outside. The method is not infallible, but it frequently serves to determine the precise size and dimensions of the gall-bladder: some normal appearances are depicted in *Figs. 693-697*.

The gall-bladder may be deformed by adhesions, or distended without obstruction to the ducts; both the shape and size may be determined when the contents are rendered opaque by means of sodium tetraiodophenolphthalein, and it is not solely in gall-stone cases that the method is of use. Gall-stone cases are, however, those in which the method is of special value: for whereas gall-stones may sometimes be detected by direct X-ray examination (*Figs. 357-359*, p. 441), there are many instances in which, though present, they do not show until the bile round them has been rendered opaque to the X rays by the administration of the drug. This is instanced by *Figs. 698-701*, in all of which direct examination failed to reveal stones, though they became clear enough when sodium iodo-phenolphthalein had been administered by the mouth twelve or more hours previously. *Figs. 698 and 699* serve to show that stones that may not be very apparent at 12 hours may become so a few hours later. It will be noted that the drug does not render the stones themselves opaque to the rays: it renders the bile in the gall-bladder opaque, and then the stones immersed in the bile become visible as light shadows in the darkened bile.

The sodium tetraiodophenolphthalein may be administered either orally or intravenously. Earlier cases of the intravenous method suffered from toxic symptoms, but it has been found that the latter ensue only when the solution has not been made up freshly for the occasion. The advantage of the intravenous method is that the subsequent radiogram can be taken at a shorter interval, 8 or 9 hours instead of 12 or 14 as with the oral method: besides which the shadowing given by the bile in the gall-bladder is the darker. Generally, however, the oral method is preferred. The dose for the intravenous method is 3.5 grm., dissolved in 40 c.c. of sterile distilled water, filtered, and sterilized by boiling for fifteen minutes; and the solution should be made freshly for the occasion. The patient should starve, to make the more sure that the gall-bladder remains full: and to assist gastric and duodenal rest, 40 gr. of sodium bicarbonate should be given at the time and repeated every three hours. For oral administration a rather larger dose of the dye is needed—from 4 to 6 grm. according to the weight and size of the patient—made up in capsules of $\frac{1}{2}$ grm. each or less: these are taken at night after a very light supper: 40 gr. of sodium bicarbonate are given at bedtime, and again during the night if the patient is awake. The first skiagram is taken next morning 12 hours after the sodium tetraiodophenolphthalein has been given; a second at 15 hours; others at subsequent intervals if it is desired to find out how long the gall-bladder takes to empty.

Fig. 694. Skiagram of a normal gall-bladder, the patient lying on his face, twelve hours after taking 4.5 grm. of sodium tetraiodophenolphthalein in capsules by the mouth. (By Dr. C. Thurston Holland.)

Fig. 695. Skiagram of the same normal gall-bladder as the one depicted in *Fig. 694*, fifteen hours after the taking of the sodium tetraiodophenolphthalein. (By Dr. C. Thurston Holland.)

Fig. 696. Skiagram of the same case as *Figs. 694* and *695*, eighteen hours after the taking of the sodium tetraiodophenolphthalein. The iodo-contents of the gall-bladder have already begun to disappear. (By Dr. C. Thurston Holland.)

Fig. 697. Skiagram of the same case as *Figs. 694-696* thirty-eight hours after the administration of the sodium tetraiodophenolphthalein. The iodo-compound have left the gall-bladder entirely in the normal time, and the gall-bladder is no longer visible with the X rays. (By Dr. C. Thurston Holland.)

Fig. 698. Skiagram of a gall-bladder containing many medium-size gall-stones. Direct examination with the X-rays showed no abnormality. This skiagram was taken twelve hours after the oral administration of 4.5 gm. of sodium tetraiodophenolphthalein; the gall-bladder and the stones in it are seen, faintly between the spine and the gas bubble in the hepatic flexure of the colon, but they are less evident than they became at fifteen hours. (By Dr. C. Thurstan Holland.)

Fig. 699. Skiagram from the same case as *Fig. 698*, but taken fifteen hours after the oral administration of the tetraiodophenolphthalein; it shows the gall-bladder and gall-stones more clearly than does *Fig. 698* at twelve hours. Note that the gall-stones are light; they are, as it were, negative, showing up in contrast to the darkened radio-bile around them. (By Dr. C. Thurstan Holland.)

Fig. 700. Skiagram of a long narrow gall-bladder containing multiple small gall-stones; taken twelve hours after the oral administration of 4.5 gm. sodium tetraiodophenolphthalein in fifteen capsules. Note that the gall-stones are not themselves opaque to the X-rays, but that they show up as light areas in contrast with the darkened bile in the gall-bladder. Previous to the administration of the drug no opacity could be detected. (By Dr. C. Thurstan Holland.)

Fig. 701. Skiagram of a single large translucent gall-stone in a contracted and deformed gall-bladder; taken twelve hours after the oral administration of 4.5 gm. sodium tetraiodophenolphthalein. The gall-stone was not visible until the drug was given; it shows up as a light area in contrast with the darkened bile around it. (By Dr. J. H. Mather.)

Herbert French.

INDEX

Large heavy type thus 'ASCITES'—refers to main articles; smaller heavy type 'Abdominal phlebitis'—to pages on which there is more than a mere note on the condition indicated; ordinary type 'Abscess, cold'—to pages on which the condition is merely mentioned. References to illustrations are printed in italics, enclosed in brackets, and followed without a break by the page reference, thus (Figs. 61, 62, 63) 43.

Abscess, mediastinal, contd.
 - pain behind sternum
 from .. 535
 - in back from .. 535
 - shoulder from .. 535
 - syphilitic .. 535
 - tenderness of spine
 from .. 868, 869
 - sternum from .. 535
 - tuberculous .. 535
 - military, of newborn .. 681
 - in neck from adenitis .. 474
 - omental, from gastric ulcer .. 810
 - of orbit, diplopia from .. 222
 - eye displaced by .. 222
 - parametric, felt per rectum .. 729
 - groin bulged by .. 826
 - pyrexia due to .. 687
 - vaginal examination in diarrhoea .. 693
 - parotid, after operation .. 695
 - from oral sepsis .. 695
 - pain over .. 695
 - pyrexia due to .. 687, 695
 - rarely primary .. 695
 - skin to flexed over .. 695
 - swelling of face from .. 695
 - neck from .. 695
 - in typhoid fever .. 695
 - pelvic, bearing down pain from .. 529
 - bladder irritated by .. 148
 - opened by .. 556, 716, 723
 - blood per anum from .. 96
 - from diverticulitis .. 556, 557
 - hematoma from .. 348, 556
 - due to lupus case .. 841
 - local peritonitis with .. 843
 - pain in iliac fossa from .. 555, 557
 - pelvic cellulitis simulating .. 843
 - swelling due to .. 840
 - from parietal sepsis .. 843
 - pus in abscess from .. 680
 - pyrexia due to .. 716
 - rectum, bulged by .. 843
 - invaded by .. 96
 - ruptured into rectum .. 843
 - from sigmoidoscopy .. 843
 - tenderness of spine from .. 868
 - uterus fixed by .. 841
 - vesical, elic from .. 148
 - pericardiac, pus in stools from .. 680
 - umbilicus, inflamed from .. 804
 - perineal .. 766
 - leucocytosis with .. 453
 - perinephric, account of .. 697
 - from appendicitis .. 448, 697
 - carcinoma coli .. 438
 - coli bacilluria .. 697
 - diverticulum of colon .. 438
 - empyema from .. 134
 - fluctuation in .. 438
 - from hematogenous infection .. 438
 - hematoma .. 438, 697
 - hepatic abscess from .. 464
 - after injury .. 697
 - loin bulged by .. 437, 438, 554, 697, (Fig. 535) 698
 - from loin injury .. 438
 - method of palpation .. 697
 - edema of loin over .. 438
 - pain in hypochondrium from .. 553, 554
 - loin from .. 438, 697
 - lumbar region from .. 554
 - pus in stools from .. 680
 - pyrexia due to .. 438, 687, 697
 - rigor due to .. 737
 - sense of resistance over .. 697
 - spleen simulated by .. 775
 - tenderness in loin from .. 697
 - lumbar region from .. 697
 - of spine from .. 868, 869
 - tumour due to .. 554
 - periosteal .. 817
 - necrosis of jaw from .. 834
 - pain in .. 694

Abscess, periosteal, contd.
 - pyrexia from .. 687
 - swelling on bone due to .. 694
 - in typhoid fever .. 918
 - periproctial, acute peritonitis from .. 63
 - anasthetic in diagnosis .. 874
 - anasthetic .. 874
 - ascites from .. 63
 - bladder irritated by .. 148
 - from carcinoma .. 874
 - carcinoma simulated by .. 874
 - diverticulitis simulating .. 557
 - loss of weight from .. 874
 - opening into bladder .. 296
 - pain in iliac fossa from .. 555
 - perineum from .. 693
 - from piles .. 874
 - polypus .. 874
 - proctoscope in diagnosis .. 874
 - pyrexia due to .. 687
 - rectal examination in diagnosing .. 693
 - sigmoidoscope in diagnosis .. 874
 - sleepiness from .. 874
 - stranguary due to .. 797
 - suppurative peritonitis from .. 63
 - tenesmus due to .. 873, 874
 - vesical, conic from .. 148
 - periprostatic, diverticulitis simulating .. 557
 - pain in iliac fossa from .. 555
 - stranguary due to .. 797
 - tenesmus due to .. 873
 - peritubercular, fluctuation from .. 494, 767
 - fluctuation in .. 851
 - edema over .. 851
 - scrotal swelling from .. 767
 - from structure .. 494, 767
 - tenderness of .. 851
 - from urethritis .. 767
 - popliteal .. 844
 - from glands .. 844
 - knee flexed with .. 844
 - from necrosis of femur .. 844
 - edema over .. 844
 - pain over .. 844
 - from periostitis .. 844
 - pulse rapid with .. 844
 - pyrexia with .. 844
 - skin reddened over .. 844
 - transmitted pulsation of .. 844
 - from tuberculous knee .. 844
 - post-pharyngeal .. 694
 - age incidence of .. 794
 - from cervical caries .. 694
 - in childhood .. 244
 - cyanosis from .. 196, 694
 - digital examination in diagnosing .. 694, 794
 - diphtheria simulated by .. 694
 - dysphagia from .. 244, 661
 - dyspnoea from .. 244, 246, 248, 694, 762
 - hoarseness from .. 388
 - in infancy .. 694, 762
 - laryngeal obstruction from .. 196
 - laryngismus stridulus simulated by .. 249, 799
 - larynx displaced by .. 388
 - meningitis simulated by .. 731
 - pain in ear from .. 253
 - neck with .. 694
 - pyramidal from .. 661
 - pyrexia from .. 687, 694
 - sore throat due to .. 757
 - from spinal caries .. 794
 - spinal caries simulating .. 762
 - stertor due to .. 794
 - stiff neck with .. 694
 - stridor from .. 196, 694, 799
 - tenderness of spine from .. 868, 869
 - tuberculous .. 694

Abscess, contd.
 - prostatic, account of .. 723
 - aching in perineum from .. 579
 - acute peritonitis from .. 63
 - ascites from .. 63
 - difficulty in micturition from .. 723
 - felt per rectum .. 728, 766
 - frequency of micturition due to .. 575
 - from gonorrhoea .. 228, 723
 - hamaturia from .. 723
 - after instrumentation .. 723, 766
 - micturition difficult with .. 575
 - painful with .. 575
 - opening into bladder .. 716, 723
 - rectum .. 296, 723
 - pain in penis from .. 574, 576, 578
 - perineum from .. 693
 - perineal sinus from .. 766
 - prostate enlarged from .. 575
 - with prostatic calculus .. 723
 - from prostatitis .. 296, 723
 - pyrexia due to .. 575, 687
 - pyuria due to .. 716, 723
 - rectal examination in diagnosing .. 575, 693, 715
 - retention of urine from .. 493, 723
 - rigors from .. 723
 - scarring after .. 766
 - soft area in prostate due to .. 723
 - sore in perineum from .. 766
 - suppurative peritonitis from .. 63
 - tuberculous .. 723
 - urethral discharge from .. 766
 - from urethritis .. 575, 723, 766
 - venereal causes .. 766
 - psoas, account of .. 458
 - anasthetic with .. 47
 - appendicitis simulated by .. 565
 - bilateral .. 831
 - chest bulged by .. 210
 - external to femoral vessels .. 841
 - femoral hernia simulated by .. 825, 831
 - fluctuation in .. 458, 698, 825, 831
 - groin abscess due to .. 831
 - hip disease simulated by .. 458
 - iliac abscess distinguished from .. 831
 - ilio-psoas bursa simulated by .. 826
 - impaired movement of back with .. 825
 - impulse on coughing in .. 825, 831
 - kyphosis and .. 698, 825
 - lameness due to .. 868
 - lardaceous disease from .. 469
 - limping from .. 457
 - lipoma simulating .. 831
 - notes on .. 698
 - opened, leucocytosis slight in .. 453
 - pain in back from .. 698
 - iliac fossa from .. 555, 558
 - leg from .. 868
 - spine with .. 458
 - pointing in back .. 868
 - Scarpa's triangle .. 825
 - Pott's angular curvature with .. 458
 - below Poupart's ligament .. 831
 - pus in stools from .. 680
 - pyrexia due to .. 687, 698
 - pyuria due to .. 716
 - reducible .. 825, 831
 - rigidity of back with .. 458
 - spine with .. 698, 831
 - ruptured into bladder .. 716, 723, 724

Abscess, psoas, contd.
 - ruptured into ureter .. 724
 - saphena varix simulated by .. 825
 - sciatica distinguished from .. 82
 - secondary infection in .. 698
 - spinal caries and .. 628, 698, 724, 831
 - deformity with .. 831
 - swelling in groin from .. 458, 698
 - iliac fossa from .. 724, 814
 - inguinal region from .. 724
 - tenderness in groin from .. 698
 - spine with .. 458, 831
 - thigh flexed with .. 458
 - tuberculous .. 698
 - ureteral calculus simulated by .. 565
 - X rays in diagnosing .. 458, 698
 - in the young .. 698
 - pyæmia from .. 738, 740
 - pyæmic, leucocytosis with .. 453
 - quinsy .. 758
 - rectal, account of .. 727
 - renal (see Abscess of Kidney)
 - residual, pyelophlebitis simulating .. 696
 - retropharyngeal (see Abscess, Post-pharyngeal)
 - of rib .. 210
 - rigor with .. 740
 - round colon .. 812
 - sacro-iliac, swelling in iliac fossa due to .. 814
 - of sacrum, rectal examination in diagnosing .. 729
 - scrotal .. 767
 - from tuberculous epididymis .. 851
 - septicæmia from .. 740
 - of spine, intercostal pain from .. 531
 - tenderness from .. 862
 - tenderness of spine from .. 868
 - spleen, general peritonitis from .. 734
 - subcutaneous, leucocytosis with .. 453
 - in pyæmia .. 738
 - subdiaphragmatic .. 697, 807
 - abdominal swelling due to .. 804, 807
 - adhesions round .. 461
 - albumosuria from .. 20
 - from appendicitis .. 133, 137, 555, 807
 - Bacillus coli in .. 649, 800
 - bronchiectasis after .. 367
 - cæcogæstria due to .. 860
 - from carcinoma coli .. 649
 - of stomach .. 647, 649
 - chest bulged by .. 210
 - coin sound in .. 555
 - communicating with duodenum .. 800
 - stomach .. 800
 - costophrenic angle not obliterated by (Fig. 116) .. 133
 - cough from .. 188
 - diaphragm immobilized by .. 807
 - pushed up by (Fig. 116) .. 133, (Fig. 623) 801, 807
 - from duodenal ulcer .. 555, 649, 807
 - emaciation due to .. 697
 - empyema from .. 133, 134, 807
 - simulated by .. 695, 697
 - epigastrium bulged by .. 807
 - from Fallopian tube suppuraton .. 807
 - fibroid lung after .. 367
 - foul sputum from .. 790
 - friction due to .. 697, 807
 - gas in .. 555, 647, 649, 800, (Fig. 623) 801, 807
 - from gastric ulcer .. 133, 555, 647, 649, 807
 - heart displaced by .. 801, 807

<i>Abcess, subdiaphragm. contd.</i>	<i>Abcess of testis, contd.</i>	<i>Acetone, contd.</i>	<i>Aching in loins, contd.</i>
- from hepatic abscess .. 555, 807	- in mumps .. 768	- headache from .. 371	- from coli bacillus .. 699
- hepatic abscess simu- .. 807	- from orchitis .. 768	- Legal's test for .. 3	- contralateral, in kid- .. 448
- hicough from .. 387	- pain in testis from .. 768	- nitroprusside test for .. 3	- from hypernephroma .. 449
- hydropneumothorax .. 800	- pyrexia in .. 768	- oxybutyric acid with .. 3	- malignant kidney .. 448
- simulated by .. 800	- rigor from .. 768	- Rothera test for .. 3	- oxaluria .. 353
- hypochondrium bulged .. 807	- in scarlet fever .. 768	- tests for .. 3	- phosphatic diabetes .. 637
- by .. 807	- scrotal sinus from .. 768	- illustrated (Figs. 2-8) .. 4	- polycystic kidneys .. 450
- impaired note from .. 697	- sore from .. 768	ACETONURIA .. 4	- pyelitis .. 718
- insidious .. 807	- testis enlarged by .. 585	- acidosis indicated by .. 3, 341	- renal calculus .. 351, 719
- from kidney suppu- .. 807	- tender with .. 768	- from alcoholism .. 3, 341	- tumour .. 351
- tion .. 807	- from torsio testis .. 768	- anaesthetics .. 3	- tuberculous kidney .. 352, 719
- after laparotomy .. 555	- urethral discharge .. 768	- cachexia .. 3	- ureteral calculus .. 720
- leucocytosis with .. 807	- with .. 768	- causes of .. 3	- vesical tumour .. 349
- liver displaced by .. 461	- from urethritis .. 768	- from cerebellar tumour .. 3	- lumbo-sacral, from pyo- .. 724
- dullness raised with .. 462	- in thyroid gland .. 877	- cerebral tumour .. 3	- in rectum from carci- .. 727
- not pushed down .. 555	- tonsillar, enlarged gland .. 694	- cerebrospinal meningitis .. 4	- noma recti .. 727
- needing in diagnos- .. 697, 807	- with .. 694	- from concussion .. 3	- testis from hydrocele .. 588
- opening through dia- .. 647	- leucocytosis from .. 454	- cyclical vomiting of .. 3, 928	<i>Achlorhydria in achylia</i>
- after operation .. 807	- pain in ear from .. 254	- in delayed chloroform .. 3	gastria .. 341
- operation in diagnos- .. 697	- pyrexia due to .. 454, 687	- poisoning .. 3	- cachexia .. 341
- ing .. 697	- typhoid fever simu- .. 454	- from delirium tremens .. 3	- carcinoma of stomach .. 344
- pain in chest from .. 530	- lated by .. 454	- in diabetes .. 331, 655	- cirrhosis of liver .. 341
- shoulder from .. 580, 583	- and see Quincke .. 593	- diacutaria and .. 214	- combined sclerosis of .. 341
- from pancreas sup- .. 807	- umbilical, in tubercu- .. 593	- from encephalitis leth- .. 4	- cord .. 341
- physical signs of .. 697	- urethral, achine in peti- .. 579	- argia .. 3	- enterica .. 341
- pleurisy from .. 697, 807	- Absent, coma from .. 154	- gastrectasis .. 3	- fevers .. 341
- simulated by .. 697	- heart irregular from .. 596	- gastric carcinoma .. 3	- fractional test meal in .. 344
- pleuritic effusion from .. 137	- palpitations from .. 594, 596	- crises .. 3	- in heart disease .. 341
- pneumonia simulated .. 697	- tremor due to .. 879, 881	- ulcer .. 3	- from new growth .. 316
- by .. 697	Absolute alcohol (see	- without glycosuria .. 3	- in normal people .. 341
- pneumothorax from .. 647, 649	Alcohol .. 206	- in health .. 3	- pernicious anemia .. 341
- simulated by .. 807	- bone-conduction test .. 206	- from infantile diarrhoea .. 3	- Fig. 286 .. 347
- pulse rapid with .. 807	- of hearing .. 206	- and vomiting .. 3	- pneumonia .. 341
- from pus in chest .. 807	Absorption band (see .. 663	- intestinal obstruction .. 3	- toxæmia and .. 303
- pyelphlebitis simu- .. 696	Spectrum .. 663	- intracranial lesions .. 3	<i>Achloruric acute yellow</i>
- pyopneumopericar- .. 800	A-c Interval .. 663	- iodoforn test for .. 3	atrophy .. 416
- pyrexia due to .. 555, 687, 697, 807	Academy headache .. 372	- from malaria .. 3	<i>Achloruric jaundice (see</i>
- râles with .. 697	Acanthosis nigricans, car- .. 646	- malignant cachexia .. 3	Jaunice, Acholuric .. 233
- rigors due to .. 737, 807	- cinoma of stomach and .. 646	- mucætic .. 3	<i>Achlorion quinquæannu .. 309</i>
- septic aspect with .. 807	- facies of .. 295	- desophageal stenosis .. 3	- Schœnleuma .. 309
- serous effusion in .. 133	- finger affected by .. 401	- after operations .. 3	<i>Achylia, achlorhydria in</i>
- shortness of breath .. 807	- illustrated (Fig. 257) .. 205	- from persistent vomit- .. 3	- in ataxic paraplegia .. 631
- skiagrams of .. 133, 801	- pigmentation of skin .. 646	- ing of pregnancy .. 3	- combined sclerosis of .. 631
- (Fig. 116) .. 133, 801	Acaras scabiei, burrows of .. 650	- ptomaine poisoning .. 3	- cord .. 631
- Skodaic resonance .. 755	- eosinophilia from .. 272	- syphilis .. 3	- diarrhoea with .. 216
- from suppurating .. 807	- on fingers .. 659	- tabes dorsalis .. 3	- dyspepsia from .. 399
- hydatid cyst .. 807	A.C.C. greater than .. 3	- tuberculous cachexia .. 3	- in gastritis .. 398
- tenderness in epi- .. 807	K.C.C. in Erb's sign .. 3	- meningitis .. 3	Acid, acetic, in albumin
- hypochondrium .. 807	ACCENTUATION OF .. 1	- uræmia .. 3	test .. 5
- of spine from .. 868, 869	HEART SOUNDS .. 1	Acetylene blowpipe, eye- .. 547	- examining stools .. 215
- epiphanic note over .. 555	- and see Heart .. 1	- strain from .. 547	- gastric juice .. 401
- ulcer of colon .. 807	Accessorius, nerve-supply .. 609	- workers, dermatitis in .. 917	- glacial, in benzinidic .. 104
- umbilicus inflamed .. 804	Accladium, castellani .. 312	- Achalasia of anal sphincter .. 163	- extracting blood .. 104
- vomiting from .. 188	Accommodation, difficult .. 84	- cardiac, account of .. 243, 244	- pigment .. 104
- X rays in diagnosing .. 555, 649, 697, 801, 807	- from ciliary muscle .. 84	- barium and X rays .. 244	- testing for por- .. 903
- submammary, breast .. 838	- after diphtheria .. 84	- in diagnosing .. 243	- phyrin .. 903
- pushed forward by .. 838	- paralysis of, in dis- .. 923	- (Figs. 207, 208) .. 243	- Hofmeister's test .. 3
- pain due to .. 529	- reflex of pupil .. 674	- of œsophagus, barium .. 244	- Legal's test .. 20

- after .. epididymo- .. 585	Acetate of cellulose in .. 416	Aching all over in influ- .. 692, 712	- dermatitis from .. 915
- from gonorrhœa .. 768	- aeroplane varnish .. 416	enza .. 692, 712	- diazo-reaction from .. 218
- instrumentation .. 768	- lead in Cammidge's test .. 129	- Kirkland's disease .. 702	- erythema from .. 275
	- sodium in phenyl- .. 328	- serum disease .. 277	- Fehling's solution .. 327
	- hydrazone test .. 328	- trench fever .. 786	- ferric chloride reac- .. 214
	- theocin, polyuria .. 653	- in back in phosphatic .. 637	- hematuria from .. 348
	- zinc in urobilin test .. 407	- diabetes .. 637	- hamoglobinuria from .. 357
	Acetic acid (see Acid) .. 407	- at external abdominal .. 768	- hysterical patient and .. 124
	Aceto-acetic acid (see Acid, .. 407	- ring, from abscess of .. 768	- malingering using .. 124
	Diacetic) .. 407	- testis .. 768	- ochronosis from .. 906
	Acetone, acidosis and .. 3, 330	- above eye, from frontal .. 722	- for pediculi .. 906
	- in aeroplane varnish .. 416	- empyema .. 226	
	- breath .. 330	- general, in syphilis .. 686	
	- in diabetes .. 213	- in limbs in paralysis .. 881	
	- cyclical vomiting .. 479	- agitans .. 881	
	- diacetic acid with .. 3	- peripheral neuritis .. 550	
		- loins, with anuria .. 57	
		- from carcinoma of .. 722	
		- bladder .. 722	

Acid, carbolic, contd.

- poisoning by, hypothermia in	392
- scales due to	744
- smell in recognizing	929
- tinea simulated by	276, 312
- in Uffelmann's reagent	401
- for ulcus serpens	891
- in urine	214
- cholalic	299
- chronic, hemoglobinuria from	357
- chrysophanic, in aperients	904
- pink urine after	904
- red urine due to	903
- in rhubarb	903
- senna	904
- urine, test for	401
- Congo-red test for	915
- dermatitis due to	3
- diacetic, with acetone	3, 330
- acidosis and	3
- cause of, in urine	3
- in cyclical vomiting	479
- ferric chloride reaction for	Fig. 184
- significance of	3
- from starvation	3
- test for	214
- in urine - see Diacetic	
- eruptions from dyspepsia	400
- fatty, in gangrene	818
- method of estimating	299
- in stools	216
- normal amounts of	300
- gallic, thirst due to	875
- urine black from	904
- gangrene from	317
- glucic, acetic - see Acid, Acetic	
- glyconic, Bial's test	327
- from drugs	332
- Fehling's solution reduced by	327, 332
- osmic crystals from	328
- phenylhydrazine and	129
- phloroglucin test and	327
- hematine, spectrum of	Fig. 21, 13
- hippuric, Fehling's solution reduced by	327
- homogentinic, in alcaptonuria	905
- estimation of	906
- Fehling's solution reduced by	905
- from phenylalanine	905
- tyrosine	905
- in urine	905
- hydrochloric, absent from gastric juice in carcinoma of stomach	44, 547, 930
- combined sclerosis	177
- pernicious anemia	177
- some normal people	341
- various conditions	44
- in Bial's test	327
- blood per anum from	103
- in Cammidge's test	129
- carboluria test	906
- diarrhoea controlled by	216
- in diazo-reaction	217
- fat estimation	299
- free, Gunzburg's test for	Fig. 318
- in gastric juice	401
- in carcinoma	802
- deficient in achylia gastrica	341
- cachexia	341
- carcinoma of stomach	341, 397, 777
- cirrhosis of liver	341
- combined sclerosis	341
- dilated stomach	930
- enterica	341
- fevers	341

Acid, hydrochloric, contd.

- in gastric juice, deficient in gastritis	998, 930
- heart disease	341
- pernicious anemia	341
- pneumonia	341
- in gastric ulcer	930
- high, in duodenal ulcer	554
- in pyloric stenosis cases	930
- tests for	401
- hemoglobinuria from	357
- homicide by	103
- increased in gastric juice - see Hyperchlorhydria	
- in indican test	395, 905
- Perle's test	31, 335
- phloroglucin test	327
- phargoric hydrogen	421
- suicide by	103
- in testing for porphyrin	903
- hydroquinone, etc., in alcaptonuria	905
- from phenylalanine	905
- tyrosine	905
- in urine	905
- lactic, in gastric juice	401
- in carcinoma of stomach	497
- Uffelmann's reagent for	401
- in vaginal secretion	231
- vomit in dilated stomach	930
- gastric carcinoma	930
- methyl orange test for	401
- methyl-salicylic, crystalline from	275
- nitric, in albumin test	5
- albumose test	12, 20
- bile test	903
- blood per anum from	103
- bulle from	123, 124
- fallacies of test for albumin with	6, 7
- haemoglobinuria from	357
- homicide by	103
- hysterical patient and	124
- indican in	395
- blackened by	904
- brown ring with	6
- malingerer using	124
- in melanuria test	905
- nucleoproteid dissolved by	5
- suicide by	103
- test for indican	905
- ulcer of leg from	894
- white ring with albumose	22
- osmic, fat stained by	140
- oxalic, acute nephritis from	11
- anuria from	55
- coma from	154
- corrosive poisoning by	338
- crystals - see Crystals	
- haemoglobinuria from	357
- poisoning	348
- anuria from	55
- hypothermia in	392
- strangury due to	798
- (and see Oxaluric)	
- oxybutyric, with acetone	3
- acidosis and	3
- in urine	3
- phosphotungstic, in Hotteimer's test	20
- picramic, from picric acid	903
- in urine	903
- picric, acute yellow atrophy from	416
- dermatitis due to	917
- in explosives	408
- jaundice due to	421
- in leydite	917
- malingerers using	917
- in melinite	917
- picramic acid from	903
- yellow sclerotics from	421
- skin from	645
- urine after	903

Acid, picric, contd.

- yellow vision due to	926
- prussic, smell in recognizing	929
- pyrogallie, dermatitis due to	917
- erythema due to	275, 918
- haemoglobinuria from	357
- oedema due to	918
- used in photography	917
- risings into throat	376
- salicyl-sulphonic, test for albumin	7
- salicylic, purpura from	676
- vesicles due to	918
- sore throat due to	758
- stearic, fat expressed as	299
- succinic, leucocytosis from	453
- sulphuric, in diazo-reaction	217, 218
- sulphuric, blood per anum from	103
- haemoglobinuria from	357
- homicide by	103
- in Huppert's test	903
- suicide by	103
- in Ziehl - Neelsen staining	788
- tannic, thirst due to	875
- tartaric, in inflating stomach	307, 399, 400
- Speigler's test	7
- trichloroacetic, albumin precipitated by	20
- in blood-urea estimation	20
- uric, acidity of urine and	901
- adenin and	901
- alloxuric bodies and	901
- from biliousness	901
- in birds	901
- bove	901
- calcium oxalate and	901
- calculus and	900, 902
- in bladder	Fig. 22
- not opaque to X rays	4
- carmin and	901
- cayenne-pepper deposit due to	900
- in chronic heart disease	901
- clinical significance of	901
- the clinker of body	901
- crystals of - see Crystals	
- from deficient exercise	901
- diet and	901
- diminished in acute yellow atrophy	416
- dumb-bells of	900
- endogenous	901
- epiguanin and	901
- episarkin and	901
- exogenous	901
- Fehling's solution reduced by	327, 902
- in fevers	901
- frequency of micturition and	901
- glycosuria and	901
- gout and	901
- gravel due to	900
- guanin and	901
- heteroxanthin and	901
- hypoxanthin and	901
- in leukemia	901
- methylxanthin and	901
- microscope in diagnosing	900
- mucus with	900
- nucleoproteins and	901
- from overeating	901
- oxaluric and	523
- paraxanthin and	901
- in pernicious anemia	901
- phosphates and	901
- purin bodies and	901
- renal calculus and	901
- rosettes of	900
- in subacromial bursa, skiagram	(Fig. 38) 428
- urates confused with	900
- urea and	901
- urethritis and	901
- IN URINE	900
- urochrome in	900

Acid, uric, contd.

- whetstones of	900
- X rays in	(Fig. 338) 428
- xanthin bases and	901
- Acid-fast bacilli	788
- in leprosy	82
- Acidity of urine (see Urine)	
- Acidosis, acetone and	3, 330
- in breath in	3
- acetoneuria indicating	400
- in alcoholism	331
- from chloroform	416
- in cyclical vomiting	211, 479, 928
- delirium from	211
- in diabetes	211, 330, 331, 334
- diacetic acid and	3, 330
- glycogen and	4
- in glycosuria	330
- headache from	371
- in marasmus	479
- nature of	3
- oxybutyric acid and	3
- in severe vomiting of pregnancy	211
- sweet-odoured breath in	330
- Acne in asphalt workers	917
- from chlorine	917
- decalvans	865
- from naphtha	917
- parafin	917
- rosacea, achlorhydria with	303
- acne vulgaris distinguished from	303, 600
- age incidence of	303
- from alcohol	303, 881
- butterfly face of	303
- in cirrhosis of liver	67
- in comedones in	303
- congestion in	600
- cornal ulcer with	890
- due to dyspepsia	303
- of face	881
- flush area of face	600
- affected by	600
- flushing causing	303
- granulosus rubra nasi distinguished from	803
- leprosy simulating	501
- lupus erythematosus distinguished from	303
- in middle life	600
- seborrhoeic eczema distinguished from	303
- syphilis distinguished from	304
- due to tea	3
- telangiectasis with	303
- of scalp	885
- septicemia from	785
- from tar	917
- tenderness of scalp from	865
- vulgaris, account of	600
- age incidence of	600
- blackheads in	600
- bromide rash distinguished from	125
- simulating	682
- cheloid from	131
- comedones in	303, 683
- of face	862
- forehead	865
- iodide rash distinguished from	125
- simulating	682
- milium in	600
- of neck	865
- papules in	598, 600
- parts affected by	600, 683
- pre-auricular gland enlarged from	473
- at puberty	303, 682
- pustules in	125, 600, 681, 688
- rosacea distinguished from	303, 600
- scar from	131
- small-pox simulating	682, 686
- syphilis distinguished from	682
- syphilis simulating	683
- xanthoma simulating	889
- Acnitis	683
- Acnitis, bradypnoea from	110
- coma from	110
- delirium from	212

Aconite, contd.

- heart failure and .. 68
- heart-block from .. 668
- inflamed fauces in .. 761
- palate in .. 761
- uvula in .. 761
- joint pains in .. 136, 282, 758, 844
- without joint pains .. 263
- leucocytosis in .. 453
- mediastinal fibrosis from .. 68, 910
- mediastinitis from .. 386
- mitral stenosis from .. 69, 595, 857
- myocardial changes in .. 53
- myocarditis with .. 263, 264
- nausea in .. 759
- nodules in .. 136, 282, 423, 502
- oedema of legs and .. 68
- palpitation in .. 263
- psychosis rheumatica in .. 136
- pericarditis in .. 68, 71, 136, 423, 568, 758
- pleurisy in .. 68, 71, 568, 758
- pleuritic effusion from .. 136
- polyarthromenitis from .. 138
- precordial pain in .. 263
- pyrexia in .. 282, 568, 704

Acute rheumatism, contd.

- salicylates in .. 45, (Fig. 328) 423, 568
- in diagnosing .. 282, 758, 844
- relieving .. 282, 758, 844
- scarlet fever simulated by .. 282, 759
- **sennumembranosus** .. 844
- bursa in .. 136
- skin affections in .. 136
- sore throat in .. 282, 568
- thyroid gland enlarged in .. 877
- tonsillitis in .. 136, 423, 758, 759
- toxæmia from .. 261
- trichinosis simulating .. 569
- valvular disease from .. 17, 68, 136
- vomiting in .. 759
- and see Fever, Rheumatic
- **rheumatoid arthritis (see Arthritis, Rheumatoid)**
- subcutaneous lymphangitis .. 197, 606
- **yellow atrophy of liver, account of** .. 345, 416
- acholuria in .. 416
- from acroplasia .. 345, 416
- albumosuria in .. 21
- asthenia in .. 93
- bile pigment in .. 345
- urine in .. 345
- bleeding gums in .. 93
- catarrhal jaundice simulated by .. 345, 416
- childbirth and .. 416
- cholelith from .. 213
- coma in .. 153
- constipation in .. 416
- delirium in .. 213, 345
- drowsiness in .. 345
- duration of .. 416
- emotion and .. 345
- epistaxis in .. 345, 416
- females affected by .. 345, 416
- fright and .. 345, 416
- hæmatemesis in .. 336, 345, 416
- hæmorrhages in .. 416
- hyperpyrexia in .. 390
- jaundice from .. 345, 408, 416
- icterum in .. 345, 416
- and tyrosin in .. 928
- liver dullness diminished in .. 445, 416, 460
- melana in .. 345, 416
- mental emotion and .. 416
- metrorrhagia in .. 416
- from microbes .. 345
- toxæmia .. 345, 416
- nausea in .. 345, 416
- occupation and .. 345
- pain in right hypochondrium in .. 416
- petechia in .. 345
- phosphorus poisoning simulated by .. 421
- from poisons .. 416
- pregnancy and .. 345
- pulse rapid in .. 416
- pyrexia in .. 416
- sordes in .. 93
- from streptococci .. 416
- tetrachlorethane .. 416
- tongue dry and .. 345, 416
- brown in .. 345, 416
- from trinitrotoluol .. 345, 416
- tyrosin in .. 345, 416
- urea diminished in .. 345, 416
- uric acid diminished in .. 416
- vomiting in .. 345, 416, 928
- yellow fever simulated by .. 420
- zymotic diarrhoea .. 101
- Adder bite, delirium from .. 211

Adder bite, contd.

- disease simulating	642
- tumour of suprarenal not producing	776
- vertigo in	911
- vomiting in	45, 641, 928
Adductor muscles see under Muscles	
Adenin, uric acid and	901
Adenitis, epidemic cervical (see Krikland's Disease in scarlet fever)	281
- suppurative, from tonsillitis	474
- (and see under Lymphatic Glands)	
Adenoids, acustia due to	859
- anosmia due to	756
- cachexia from	127
- in children	712
- cough from	186
- earache from	253
- epistaxis from	273, 274
- headache from	370
- insomnia due to	403
- from mouth-breathing	225, 761
- night terrors from	403
- nightmares from	499
- otitis media from	253
- otorrhoea due to	522
- pyrexia due to	712
- removal of, paralysis of palate after	730
- rhinitis with	225
- sniffing tic from	173
- snoring due to	757
- stertor from	794
- taste affected from	860
- tonsillitis with	761
- and tonsils, enuresis with	270
Adenoma, fibrous (see Fibro-adenoma)	
- of liver, hyarid simulated by	469
- prostate felt per rectum	728
- of hamaturia from	348, 355
- (and see Prostate, Enlarged)	
- rectum, carcinoma simulated by	874

Adenoma of rectum, contd.

- microscope in diagnosing	874
- proctoscope in diagnosing	874
- tenesmus due to	873
- thyroid gland	877
- of cyst simulating	876
Adenomatous polipe	876
Adenomyoma of ovary	238
- uterus, pelvic swelling due to	840
Adherent pericardium, account of	70, 265, 535
- acute rheumatism and	70, 71
- angina pectoris from	864
- ascites from	62
- Broadbent's sign of	71, 265
- in children	17
- chronic mediastinitis and	70, 71
- clubbed fingers from	142
- diagnosis guessed at	266
- diastolic collapse of veins with	265
- shock with	265
- difficulty of diagnosis	69
- dilated superficial veins with	265
- dyspnoea from	246
- heart enlarged from	2, 17, 70, 71, 265
- failure from	17, 62, 69, 70, 246
- impulse displaced with	265
- fixed in	70
- hiccough from	386
- without ill effects	70
- left ventricle enlarged from	258
- mediastinal fibrosis with	265
- mitral regurgitation from	258, 263, 265
- oscillating impulse	71
- palpitation from	594
- pericarditis and	70, 71
- physical signs	70, 71, 265
- pleurisy and	71
- in polyserositis	138
- precordial bulging with	210, 265
- presystolic bruit from	266
- prolonged first sound with	2
- pulsus paradoxus with	664
- rib retraction from	71
- shortness of breath from	113
- systolic bruit with	265
- retraction with	265
- varieties of	70
- without signs	71
- symptoms	71
Adhesions, abdominal, from abscess of liver	68
- of borborygmi from	107
- in chronic peritonitis	63
- from gall-stones	409
- intestinal obstruction from	167, 168, 485
- of fainting due to	297
- jaundice due to	407
- meteorism from	485
- metastasis powerful above	107
- from peritonitis	167
- subphrenic abscess	461
- tuberculous peritonitis	167, (Fig. 563) 705
- of vomiting from	168
- after appendicitis	163, 562
- appendicular, colic from	148
- pain in iliac fossa from	558
- carcinoma of caecum simulated by	563
- from caseous mesenteric glands	167
- constipation from	163
- diaphragmatico-pericardial	71
- from disease of female pelvic organs	163
- duodenal ulcer	163
- gastric, colic from	148

Adhesions, contd.

- from gastric ulcer	163
- intestinal, in tuberculous peritonitis	806
- of iris, due to corneal ulcer	890
- joint, contracture from	179
- from gonorrhoea	179
- rheumatism	179
- rheumatoid arthritis	179
- spondylitis deformans	179
- tuberculosis	179
- after local peritonitis	163
- mediastinal	70, 71
- obstruction from	167
- operation in diagnosing	562
- pain in iliac fossa from	562
- pelvic, after abortion	573
- from appendicitis	573
- dyspareunia from	239
- from extra-uterine gestation	573
- after labour	573
- pelvic pain from	573
- rectal examination in diagnosing	168
- from salpingo-oophoritis	249, 573
- torsion of ovarian cyst	573
- pericaecal, pain in iliac fossa from	558
- pericardial	70
- heart enlarged from and see Adherent Pericardium	374
- perigastric, pain in epigastrium from	538
- pleural, diaphragm deformed by	(Fig. 119) 135
- dyspnoea from	404
- insomnia from	404
- pain in chest from	512
- neck from	512
- shoulders from	87
- spine from	87
- pneumothorax prevented by	648
- round empyema	649
- skiagrams indicating	(Fig. 119) 135, 375
- tenderness of spine from	871
- pleuro-pericardial	70, 71
- bruits from	70
- post-irritic, irregular pupil from	674
- pyloric, without apparent cause	218
- dilatation of stomach from	218
- from duodenal ulcer	218
- gall-stones	218
- gastric ulcer	218
- pyloric stenosis from	218
- shoulder-joint, paralysis of circumflex nerve simulated by	617
- uterine, colic due to	148
- X rays in cases of	163
Adhesive phlephlebitis	334
Adiposis dolorosa	509
- alcoholism and	530
- brachial neuritis simulated by	544
- generalized tenderness in	509
- lipomatosis in	804
- loss of strength in	509
- mental symptoms in	509
- myxoedema simulated by	510
- obesity from	505, (Fig. 398) 509
- pain in chest in	530
- small hands and feet in	(Fig. 398) 509, 530
- in women	530
Adolescence, albuminuria of	81
- kyphosis in	194
- rickets in	305
Adrenal (see Suprarenal)	
Adrenalin, asthma relieved by	654
- in cystoscopy	350, 722
- as styptic	722
Aegophony above pleuritic effusion	209
Aerophagy	302

Aerophagy, contd.

- diagnosis of	308
- eructatio nervosa from	397
- flatulence due to	308, 320
- pain in hypochondrium from	553
- sense of fullness and	308
- X rays in diagnosing	308
Aeroplane compass paint, selenuretted hydrogen from	421
- dopes, acetate of cellulose in	416
- acetone in	416
- acute yellow atrophy from	345, 416
- benzol in	416
- cholama from	213
- coma from	153
- delirium from	213
- epigastric pain from	416
- flatulent dyspepsia from	416
- gastro-intestinal symptoms from	416
- ill health from	416
- jaundice from	408, 416
- loss of appetite from	416
- tetrachlorethane in	416
- vomiting from	416
- fainting in	297
- hemianopsia in	377
- pilots, ataxia in	77
- deafness in	207
- tinnitus in	878
- work, shortness of breath from	113
Aetrio-auricular malaria (see Malaria)	
Afferent impulses, paths in cord	73
Africa, Central, dysentery in	99
- East, dysentery in	99
- kala-azar in	780
- South, ankylostomiasis in	103
- Bilharzia haematobia in	356
- tick paralysis in	625
- West, dysentery in	99
- malaria from	213
After-pains, pain in pelvis due to	573
Agar-agar, constipation and	160
Age incidence of acne rosacea	303, 600
- vulgaris	303, 600
- acroparasthesia	545
- acute anterior poliomyelitis	80
- encephalitis	156
- intestinal obstruction	167
- aneurysm	241, 606, 629, 869
- anorexia nervosa	58, 934
- aortic dissec17, 259, 261	
- arteriosclerosis	204
- atheroma	204
- bulbar paralysis	606, 731
- cancerous peritonitis	65
- carcinoma of bladder	577, 722
- breast	839
- pylorus	802
- rectum	556, 727
- sigmoid	556
- stomach	340, 397
- testis	850
- thyroid gland	876
- cerebral embolism	155, 184
- haemorrhage	109, 184
- cervical caries	795
- rib symptoms	204
- chloroma	679
- chlorosis	48, 346
- chorea	170
- chronic nephritis	13
- tubal nephritis	14
- chyluria	140
- cirrhosis of liver	465
- congenital syphilis of ear	912
- syphilitic nerve deafness	207
- cystic kidneys	15

Age incidence, contd.

- of diabetes mellitus	334
- in diabetic prognosis	329
- of diverticulitis	161,
556, 698	
- embryoma of testis	850
- emphysema and bron-	
chitis	17
- enlarged prostate	
355, 490, 493	
- epistaxis	274
- epithelioma	475
- of bladder	355, 721, 722
- penis	765
- tongue	896
- erythema nodosum	507
- erythromelalgia	542
- exostosis of femur	845
- faecal impaction	217
- tumour in colon	777
- femoral hernia	825, 832
- fibro-adenoma of	
breast	839
- Friedrich's ataxy	
145, 176, 624	
- gall-stones	396
- gastric ulcer	48, 339
- glaucoma	288
- gout	428
- Graves' disease	876
- hamaturia	349
- hemiplegia	382
- Henoch's purpura	
428, 680	
- hepatic abscess	464
- Huntington's chorea	171
- hysteria	58, 799
- ichthyosis hystrix	599
- inguinal hernia	832
- intermittent claudica-	
tion	542
- hydrarthrosis	433
- intussusception	101,
727, 828, 872	
- keratomalacia	891
- kraurosis vulvæ	855
- Leber's optic atrophy	923
- leukoplakia vulvæ	855
- lichen scrofulosorum	598
- Little's disease	169
- lupus erythematosus	865
- vulgaris	225, 892, 895
- lymphatic leukaemia	33
- Mooren's ulcer	891
- myocardial affections	
17, 69	
- myositis ossificans	180
- neuralgia after herpes	531
- noises in head	504
- œsophageal pouch	242
- osteitis deformans	819
- osteo-arthritis	431
- osteogenesis imper-	
fecta	233
- oxaluria	524
- Paget's disease of	
bone	887
- paroxysmal hæmie-	
globinuria	358
- peliosis rheumatica	680
- periosteal sarcoma	821
- perleche	460
- phantom tumour	61
- physiological albu-	
minuria	18
- poly-cystic kidney	450
- post-pharyngeal ab-	
scess	244, 694, 794
- primary muscular	
dystrophy	78
- progressive muscular	
atrophy	80
- prurigo	601
- pseudo-angina	533
- pseudo-bulbar para-	
lysis	731
- pseudo-leukaemia	50
- psos abscess	698
- psoriasis	602
- pytalorrhœa	662
- pupil sizes	674
- Raynaud's disease	542
- renal calculus	352
- tuberculosis	923
- retrobulbar neuritis	502
- rheumatic nodules	136
- pleurisy	428
- purpura	426
- rheumatoid arthritis	889
- rhinoscleroma	889

Age incidence, contd.

- of rickets	305, 458
- of rodent ulcer	225, 892
- sarcoma	835
- of breast	840
- testis	850
- scrofula	892
- scrofuloderma	683
- scurvy rickets	819
- shortness of breath	113
- spinal caries	868
- spine on os calcis	552
- splenomedullary leu-	
kæmia	33, 34
- splenomegalic cir-	
rhosis	780
- spondylitis defor-	
mans	870
- Stokes-Adams' dis-	
ease	183
- tetany	2
- tic douloureux	548
- tuberculous bladder	
577, 720	
- dactylitis	818
- glands	475
- joints	432
- meningitis	732
- peritonitis	64, 706, 777
- testis	587
- ulcer of tongue	898
- umbilical hernia	593
- undue pulsation of	
abdominal aorta	662
- urethral calculus	356
- urticaria	600
- vesical calculus	576, 721
- xeroderma pigmen-	
tosum	888
- sterility and	
(and see Old Age; and	
Senile)	794
- Aguesia, account of	859
- from chorda tympani	
paralysis	605
- in hysteria	754
- Agglutination, auto-, of	
blood	51
- reaction in dysentery	
99, 100, 216, 709	
- to Gaertner's bacillus	677
- in Malta fever	571, 691, 785
- for Micrococcus meli-	
tensis	785
- in paratyphoid fever	785
- in ptomaine poisoning	677
- for Shiga's bacilli	100, 216
- in typhoid fever	216
- undulant fever	455
- (and see Serum Re-	
action; and Widal)	
- Agrefphia, account of	772
- Ague (see Malaria)	
- cake spleen	779, 780
- Air hunger, account of	111
- injection in brain skia-	
graphy	936
- Air-swallowing (see Aero-	
phagy)	
- Alar chest, phthisis and	208
- Albism, leucoderma	
distinguished from	645
- nystagmus from	505
- partial	645
- photophobia from	639
- Albumin, acetic acid and	
boiling in removing	20
- in ascitic fluid	65
- cerebrospinal fluid	383
- chylous ascitic fluid	73
- mercuric chloride test	
for	7
- precipitated by alcohol	20
- salicyl-sulphonic acid	
test for	7
- Spiegler's test for	7
- trichloroacetic acid pre-	
cipitating	20
- ALBUMINURIA	
- from abdominal aneu-	
rysm	9
- accidental	18
- in acute nephritis	9,
12, 17, 57, 353	
- rheumatism	17
- of adolescence	18
- albumose with	21
- simulating	6
- with alcoholic heart	18

Albuminuria, contd.

- from alcoholism	16
- angioneurotic edema	16
- ankylostomiasis	16
- arteriosclerosis	9, 16,
390, 504, 655	
- ascending nephritis	11, 16
- ascites with	16, 64, 71
- from bacilluria	559
- bacteriuria	91
- blistering	17
- blood	15, 16
- in blood diseases	9
- from boat-race	18, 330
- boiling test for	5, 524
- from Buthrioccephalus	16
- in Bright's disease	136,
236, 263, 513, 849	
- with bronchiectasis	17, 68
- in bronchopneumonia	16
- bulbar paralysis	606
- from burns	16
- cachexia with	16, 128
- from calculus	9, 19
- catarrhes	17
- carcinoma of colon	439
- in cerebral hemorrhage	
109, 155, 382, 627	
- cholera	16
- from chronic ascending	
nephritis	9
- bronchitis	6
- nephritis	9, 13, 16, 390
- parenchymatous neph-	
ritis	506
- peritonitis	15, 64
- cirrhosis of liver	16
- cirrhotic kidneys	9
- in coli bacilluria	647,
699, 712, 933	
- conditions simulating	6
- after convulsions	181
- from corrosive poison	338
- cyclic	18
- from cystic kidney	9,
15, 655	
- in cystitis	720
- delirium with	211
- diabetes with	334
- from diabetes mellitus	16
- in diptheria	16

- bulging of chest wall by ..	210, 260
- clubbed fingers from ..	142
- colic simulated by ..	151

Aneurysm, aortic, contd.

- cough from ..	186
- cyanosis of face from ..	260
- diastolic bruit from ..	260
- dullness over ..	260
- dysphagia from ..	240
- dyspnœa from ..	246
- ear in detecting ..	260
- enlarged mediastinal glands ..	476
- first part, signs of ..	260
- heart enlarged from ..	268
- œsophagus stenosed by ..	240
- phrenic nerve irritated by ..	186
- pulsation over ..	260
- pulses unequal from ..	260
- regurgitation due to ..	260, 262
- shortness of breath from ..	114
- superior vena cava stenosed by ..	260
- systolic bruit from ..	119
- systolo-diastolic bruit from ..	260
- vagus nerve irritated by ..	186
- varicose veins on chest from ..	260
- X rays in diagnosing ..	186, 260, 476
- arm wasting from ..	82
- arteriovenous ..	122
- bruit over ..	847
- exophthalmos from ..	284
- of orbit ..	847
- pulsation due to ..	847
- asthma simulated by ..	653
- of axillary artery ..	816
- arm veins distended from ..	817
- from fungating ..	817
- endocarditis ..	817
- injury ..	817
- pulses unequal in ..	210
- back bulged by ..	534
- bloated head, neck, and arms from ..	198
- blood-pressure low in ..	472
- bone eroded by ..	846
- brachial plexus involved by ..	82, 582
- brassy cough from ..	(Fig. 169) 198, 605
- bronchiectasis from ..	366, 367
- bronchitis simulated by ..	700
- bronchus compressed by ..	323, 365, 366, 367, 534
- carotid, pupils unequal from ..	675
- cerebral, cerebral hæmorrhage due to ..	787
- convulsions from ..	184
- diabetes insipidus ..	655
- from ..	370, 371
- from infective endocarditis ..	787
- rhythmic beating from ..	371
- rushing noises from ..	371
- cervical sympathetic ..	240, 675
- affected by ..	847
- circled ..	(Fig. 631) 846
- clot in ..	321, 846
- of cardiac axis ..	413
- collapse due to ..	534
- compression, myelitis from ..	628, 629
- in paraplegia from ..	626
- cough from ..	186, 187, 188
- curvature due to ..	869
- of descending aorta, account of ..	240
- diastolic bruit from ..	122
- dissecting, abdominal pain from ..	151, 152
- colic simulated by ..	151, 152
- collapse from ..	152
- fainting due to ..	297
- pain in chest from ..	530
- peritonitis simulated by ..	152, 736
- terrible pain from ..	534
- dullness due to ..	875

Aneurysm, contd.

- dysphagia from .. 534
- dyspnoea from .. 247, 250
- **ear in detecting pulsation** 846
- eggshell crackling with .. 846
- embolism from .. 321
- eroding spine 534, 629, 814, 869, 933
- abdominal pain .. 151
- colic simulated by .. 151
- compression myelitis from .. 628
- pain in testis from .. 589
- skiagram (*Fig. 444*) 534
- expansile pulsation in .. 210, 846, 869
- of external iliac artery .. 827, 832
- extreme cyanosis from .. 198
- fatal hæmatemesis from .. 337
- femoral .. 825
- from infective endocarditis .. 787
- fibroid lung from .. 367
- fuistorm, X rays in .. 262
- gangrene from .. 317, 321
- of fingers from .. 322
- girdle pain from .. 534
- in from .. 830
- hæmatemesis from .. 336, 342
- hæmoptysis from .. 43
- 187, 361, 362, 365
- hard manual work and .. 241, 365
- headache in .. 372
- heart impulse displaced .. 373
- of heart, rupture of .. 264
- hepatic artery, ascites from .. 61, 67
- from embolism .. 67, 413
- fungating endocarditis .. 67, 413
- jaundice from .. 67, 407, 413
- portal vein obstructed by .. 61, 67
- hoarseness from .. 488
- hysteria simulated by .. 531
- of iliac artery .. 829
- bruist over .. 832
- expansile pulsation in .. 504, 832
- femoral pulse delayed from .. 832
- pain in iliac fossa .. 555, 558, 564
- thigh from .. 564
- rectal examination in .. 729
- sarcoma simulated by .. 832
- tumour due to .. 564
- impaired note due to .. 262, 365
- **Indigestion simulated by** 396, 528
- innominate, skiagram of (*Fig. 435*) .. 535
- insomnia due to .. 933
- intercostal nerves irritated by .. 241, 534
- pain from .. 241, 531
- tenderness from .. 862
- intracranial, bruit from .. 878
- laryngeal paralysis from .. 606
- leaking, fainting due to .. 297
- thirst due to .. 875
- **left lung-root obstructed by** 241
- ventricle enlarged by .. 258
- loss of weight due to .. 933
- lung compressed by .. 534
- in males .. 629
- malingerer simulated by .. 531, 572
- mediastinal fibrosis .. 198
- growth simulating .. 337
- melena from .. 97
- in men of forty-five .. 606
- muscle atrophy from .. 830
- neoplasm simulated by .. 833
- simulating .. 535
- oedema of arms from .. 512, 514, 516
- face from .. 514, 516
- neck from .. 514, 516

Aneurysm, contd.

- **oesophagus compressed by** .. 534, 927
- of orbit .. 285
- orthopnea from .. 250
- pain from .. 240
- in abdomen from .. 396
- arm from .. 534, 546
- back from .. 365, 527, 528, 869
- chest from .. 365, 530, 534, 933
- deltoid region from .. 582
- neck from .. 534
- shoulder from .. 580
- between shoulders .. 566, 567
- in spine from .. 241, 871
- palpitation from .. 595
- paralysis of vocal cord from .. 240, 388, 605
- paraplegia from .. 629
- phrenic nerve compressed by .. 534
- phthisis simulated by .. 365
- physical signs due to .. 241
- pleurisy from .. 534
- **of popliteal artery** 844, (*Fig. 649*) 845
- bruist over .. 844
- expansile pulsation in .. 844
- from infective endocarditis .. 787
- ligature of femoral artery for .. 322
- oedema of leg from .. 512
- pain in leg with .. 844
- pulse at ankle diminished with .. 844
- sarcoma simulating .. 844
- shrinking on compressing femoral artery .. 844
- varicose vein with .. 844
- vein obstructed by .. 512
- in prime of life .. 629
- pulmonary artery opened by .. 122
- pulmonary, hæmoptysis from .. 362
- pulsatile tumour from .. 629
- pulses unequal with .. 673
- pupil dilated with .. 675
- pupils unequal from .. 240, 675
- riles due to .. 365
- R.D. from .. 80
- recurrent laryngeal nerve affected by .. 240
- rib eroded by .. 534
- rigidity of back from .. 566
- ruptured into air-passages .. 534
- blanching from .. 157
- into bowel .. 157
- bronchus .. 157, 361, 362, 365
- coma from .. 154
- extreme blood loss from .. 154
- into heart .. 534
- lung .. 361, 3, 2, 365
- mediastinum .. 157
- oesophagus .. 157, 336, 337, 534
- pericardium .. 157, 534
- peritoneum .. 534
- pleura .. 534
- pulmonary vein .. 534
- retroperitoneal tissues .. 157
- spinal canal .. 534
- stomach .. 157, 336
- sudden death from .. 157, 362
- into trachea .. 157, 361, 362
- severe venous obstruction rare with .. 337
- sex incidence .. 241, 535, 869
- skiagrams (*Fig. 214*) 249, (*Fig. 219*) 260
- spinal caries simulated by .. 629
- spontaneous, in infective endocarditis .. 46
- sternum eroded by .. 210, 534
- stridor due to .. 799
- subclavian, brachial neuritis simulated by .. 544
- clubbed fingers from .. 142

Aneurysm, subclavian, contd.

- oedema of arm from .. 512
- osteo-arthropathy with .. 436
- sudden death from .. 534
- superior vena cava obstructed by .. 516, 910, 911
- opened by .. 122, (*Fig. 218*) 260, 514, 516, 910, 911
- syphilis and .. 241, 365, 535, 606, 629
- systolic bruit over .. 122
- tachycardia from .. 856
- tenderness of spine from .. 868, 869, 871
- thrill due to .. 875
- trachea compressed by .. 186, 188, 248, 534
- tracheal tugging from .. 240
- transverse myelitis from .. 486, 626
- two in same case .. 249, (*Fig. 214*) 249
- undue pulsation of aorta simulating .. 813
- unilateral sweating of head from .. 803
- unsuspected .. 114
- vagus nerve compressed by .. 534, 856
- varicose veins on chest from .. 218, 260, 911
- vein obstructed by, oedema from .. 511
- vena cava scdema obstructed by .. 909
- vertebra eroded by .. 534, 629, 933
- voice altered by .. 188
- vomiting from .. 185
- Wassermann reaction in .. 535, 629, 869
- X rays in diagnosing .. 82, 114, 188, 241, 365
- excluding .. 528, 535, 869
- Anglica, dermatitis from .. 915
- Angina abdominalis, abdominal pain from .. 151, 152, 396
- account of .. 152
- amyl nitrite and .. 396
- angina pectoris related to .. 152
- from atheroma of aorta .. 148, 151, 152, 485, 538
- colic simulated by .. 151, 152
- diuretin and .. 396, 538
- flatulence in .. 396, 538
- gastric colic from .. 148
- hæmatemesis in .. 396
- high blood-pressure and .. 538
- laparotomy in .. 152
- pain in epigastrium from .. 538
- simulating perforated gastric ulcer .. 152
- peritonitis .. 152
- tenesmus in .. 538
- therapeutic test of .. 396
- thickened arteries and .. 396
- trinitrin and .. 396
- vasodilators and .. 396
- vomiting in .. 152, 396
- **Ludovici, account of** .. 853
- angioneurotic oedema simulating .. 853
- asphyxiation in .. 853
- bacteriological examination in diagnosing .. 515
- brawny swelling of neck in .. 197
- cervical glands affected from .. 253
- cyanosis in .. 197
- dysphagia from .. 244
- dyspnoea in .. 197, 246, 853
- inability to open mouth in .. 884
- oedema of arms from .. 516
- face from .. 515, 516
- glottis in .. 853
- neck from .. 515, 516
- operation for .. 853

Angina Ludovici, contd.

- pain in ear from .. 253
- pyalism from .. 661
- pyrexia in .. 853
- rigor in .. 853
- from stomatitis .. 661, 853
- streptococci in .. 853
- stridor due to .. 799
- swelling of neck in .. 853
- tongue from .. 244, 851
- **maligna** .. 763
- **PECTORIS** .. 51
- account of .. 533
- in acute rheumatism .. 53
- from adherent pericardium .. 864
- age incidence of .. 533
- from alcoholic heart .. 18
- amyl nitrite in .. 396, 582
- from aneurysm .. 534, 535, 864
- anger provoking .. 533
- angina abdominalis allied to .. 152
- angor animi in .. 52
- with aortic disease .. 261, 654
- regurgitation .. 259, 533, 864
- aortitis .. 864
- arteriosclerosis .. 654, 864
- atheroma .. 654
- cardiospasm simulating .. 54
- clamminess in .. 533
- from coffee .. 533
- collapse in .. 533
- from coronary artery .. 375, 864
- in diphtheria .. 53
- distribution of pain in .. 396
- diuretin in .. 396
- duration of .. 533
- eructation with .. 52
- excitement provoking .. 533
- exertion provoking .. 533
- faintness in .. 533
- from fatty heart .. 18
- fibroid heart .. 18, 70, 264
- flatulence with .. 396, 533, 864
- gastric disturbance with .. 864
- with high blood-pressure .. 396, 654, 864
- indigestion and .. 396
- juvenile .. 237
- from myocardial change .. 18
- nausea in .. 52
- neurotic .. 533
- nitroglycerine in .. 582
- oesophageal spasm simulating .. 54
- pain in chest from .. 530
- fingers in .. 533
- left arm in .. 152, 396, 533, 582, 654
- shoulder in .. 152, 654
- neck in .. 533
- right arm in .. 533
- shoulder from .. 533, 579, 580, 582
- supraorbital region in .. 533
- puller in .. 533
- in pneumonia .. 533
- polyuria in .. 52, 653, 654
- in pernicious anaemia .. 53
- precordial pain in .. 152, 582, 654
- tenderness from .. 863
- in progeria .. 237
- **pseudo** .. 533
- salivation in .. 52
- sense of impending death in .. 52, 533
- sex incidence of .. 533
- no shortness of breath in .. 52
- from tea .. 533
- therapeutic test of .. 396
- from tobacco .. 53, 533
- trinitrin in .. 396
- in typhoid fever .. 53
- urine pale and abundant in .. 533
- vasodilators and .. 396
- wind with .. 52
- **Vincent's, account of** .. 760

- Angina, Vincent's, contd.**
- adenitis from .. 474
 - bacteriology in diagnosis .. 760
 - bleeding gums from .. 113, 760, 899
 - factor of breath in .. 760
 - fusiform bacilli in .. 760
 - illustrated (Fig. 599) .. 760
 - organisms (Fig. 609) .. 779

Apoplectiform	Montière's disease	208
Apoplexy, arteries thickened with		298
- asymmetry of reflexes after		298
- ataxy after		76
- blood-pressure high with		298
- from cerebral embolism		184
- hemorrhage		15, 184
- thrombosis		184
- coma in		181
- convulsions in		181, 184
- dizziness before		184
- epilepsy simulating		185
- epileptiform		184
- family history in diagnosing		298
- headache before		184
- hemianesthesia with		753
- from high blood-pressure		106
- short thick neck and		208
- simulated by Stokes-Adams' disease		183
- slight, fainting simulated by		298
- tingling before		184
- weakness before		184
- (and see Hemorrhage, Cerebral)		
Appendicitis, abdominal movement diminished in		828
- rigidity from		735
- tumour due to		812, 828
- abscess from		724, 812, 828
- account of		558
- actinomycosis of cæcum simulating		562
- adhesions from		163, 167, 562
- albuminuria with		21
- bacilluria simulating		153, 559
- bands from		167
- bladder irritated by		148
- carcinoma of cæcum simulating		562, 814
- catamenia simulating		814
- cholecystitis simulated by		554
- chronic, acute nephritis from		11
- coli bacilluria simulating		697
- colic from		148
- hunger pain from		396
- ill health from		697
- indigestion simulated by		396
- notes on		697
- resistance in iliac fossa due to		697
- tuberculous iliac glands simulating		697
- peritonitis simulating		706
- constipation in		812, 828
- from		187
- subphragmatic pleurisy simulating		532
- diarrhea from		216
- Dietl's crises simulating		814
- distention of colon simulating		560
- duodenal ulcer simulated by		554
- dysmenorrhœa simulated by		239
- ectopic testis simulating		589, 832
- effects of injury simulating		561
- emboli of lung from		137
- empyema from		133, 134, 137
- erosions of stomach in		347
- fecal vomiting due to		930
- felt per rectum		828
- fullness in right iliac fossa from		558
- gangrenous, general peritonitis from		149
- laparotomy for		149, 536
- pain in epigastrium from		536
- simulating colic		149
- gas in colon simulating		560
- gas-containing abscess from		646
- hematemesis from		347

Appendicitis, contd.	
- hematuria from	348, 356, 724
- hunger pain from	554
- increased frequency of micturition from	151, 491, 724, 828
- indicanturia in	554
- inflamed glands simulating	561, 562
- ovary simulating	814
- tube simulating	814
- intussusception simulating	829
- Lane's kink simulating	561
- left-sided pain from	556
- leucocytosis in	828
- local rigidity over	558
- malignant disease simulated by	812
- misdiagnosed	558
- movable kidney simulating	564, 814
- necrosis of rectus abdominis muscle in	561
- over	736
- notes on	828
- obstruction after	167
- operation in	558
- in diagnosing	554
- osteoarthritis of spine simulating	565
- ovarian neuralgia simulating	814
- ovariitis simulating	829
- pain in epigastrium in	558
- left iliac fossa from	555
- at menstrual period due to	829
- on micturition in	724, 828
- over	812
- in pelvis due to	573
- penis from	579
- right iliac fossa due to	356, 557, 558, 828
- shoulder from	583
- testis from	589
- pelvic adhesions after	573
- conditions simulating	560
- pain after	573
- tumour from	724
- perinephric abscess from	438, 697
- peritonitis from	151, 168, 734
- perityphlitis simulating	564
- pleural effusion from	133, 137
- pleurisy from	137
- simulating	565
- in plumbism	151
- pneumatia due to	646
- pneumonia simulating	565
- portal thrombosis from	843
- with pregnancy	843
- psaos abscess simulating	565
- pulse rapid in	558, 724, 828
- pyelephlebitis from	408
- pyosalpinx simulating	558
- pyrexia in	356, 558, 828
- pyuria due to	724
- rectal examination in	151, 356, 558, 814
- renal colic simulating	554
- enlargement simulated by	439
- rheumatoid arthritis of spine simulating	565
- right leg drawn up in	828
- right-sided abdominal rigidity from	724
- rigidity in right iliac fossa due to	828
- rigors from	724
- rupture of rectus abdominis muscle simulating	561
- sarcoma of cæcum simulating	814
- sex incidence of	554
- spastic colon simulating	161
- spinal caries simulating	565
- spondylitis deformans simulating	565
- stercoral ulcer of cæcum simulating	564
- stitch simulating	560
- subdiaphragmatic abscess from	133, 137, 555, 807
- peritonitis from	583

Appendicitis, contd.	
- superficial circumflex iliac vein congested over	558
- suppurating ovarian cyst simulating	558
- suppurative nephritis simulating	736
- perististis of ilium simulating	558
- pyelephlebitis from	415, 696, 738
- swelling in iliac fossa from	439, 828
- in tabes dorsalis	151
- tender swelling in	558
- tenderness over	554, 558, 812, 828
- tongue coated in	558, 828
- trench fever simulating	710
- tuberculous cæcum simulating	562, 828
- glands simulating	563, 712, 828
- kidney simulating	564
- tumour in right iliac fossa from	724
- twisted ovarian cyst simulating	559
- pedicle simulating	843
- typhoid fever simulating	564
- ulceration of bladder due to	724
- undue pulsation of abdominal aorta simulating	662
- ureteral calculus simulated by	724
- simulating	453, 559, 719
- urethritis simulating	559
- urine culture before diagnosing some cases of	153
- vaginal examination in	51, 814
- vesical colic from	148
- vomiting in	558, 812, 828, 929, 940
Appendicostomy in dysentery	99
Appendicular abscess	see Abscess
- adhesions, colic from	148
- pain in iliac fossa from	558
- colic	see Colic
- concretion, ureteric calculus simulated by	442, 443
- dyspepsia	400
- heartburn from	376
- glands, calcareous, colic from	148
- inflamed, colic from	148
- veins, thrombosis of, colic from	148
Appendix vermiformis, actinomycosis of	828
- adherent to bladder	724
- Fallopian tube	829
- ovary	829
- below pelvic brim	723
- concretion in, colic from	148
- felt per rectum	729
- foreign body in, colic from	148
- gaseous abscess by	254
- in hernia	834
- lesions of, pain in back from	528
- transposition of	556
APPETITE, ABNORMAL	58
- excessive, in diabetes	334
- increased, causes of	58
- loss of, in acute yellow atrophy	345, 416
- from aeroplane varnish	416
- anorexia nervosa	58, 934
- in anuria	55, 56, 57
- from carcinoma of stomach	58, 397
- in catarrhal jaundice	345, 411
- causes of	58
- in cirrhosis of liver	67
- delusions and	58
- in erythema scarlatiniforme	281
- insanity	58

Appetite, loss of, contd.	
- in lardaceous disease	57
- leukæmia	34
- melancholia	58
- phthisis	362
- rheumatoid arthritis	47
- with suppurative pyelonephritis	57
- in tuberculosis	58
- of kidney	57
- uræmia	55, 56, 396
- (and see Anorexia)	
perverted	58
- in pica	638
- voracious, from worms	123
Apple-jelly nodules in	
- lupus	225, 500, 684, 743, 891, 892, 895
Applications, dermatitis due to	915, 917
- Aqueous humour, opacities in	92, 924
- turbid, in iritis	287
- Arachnoid hemorrhage, convulsions from	183
- Arachnoiditis, dermatitis due to	915
- Aran Duchenne type of amyotrophic lateral sclerosis	619
- Arbor vitæ, dermatitis due to	916
- Aras semis in old age	387
- Aras in ecthyma	743
- secondary, from pregnancy	529
- Arxell-Robertson pupil (see Pupil)	
- Argemia	645
- facies in	295
- pigmentation in	201, 295
- from silver nitrate	295
- in silver workers	295
- Artemia triphylum, dermatitis due to	915
- Arm, abduction of, impaired, from arthritis	617
- circumflex nerve paralysis	617
- affected in Little's disease	169
- anæsthesia of (see Anæsthesia)	
- analgesia of, in tabes dorsalis	753
- ataxic, in Friedreich's	624
- athetosis of	604
- athetosis, palsy of, in syringomyelia (see Fig. 588)	753
- attitude in tetany	2
- choreiform contractions of	170
- cramps in, in carpopedal spasm	190
- cholera	190
- in ectromelus	234
- erythema nodosum affecting	502
- populatum affecting	600
- flushing of, in brachial neuralgia	543
- gangrene of	318
- in diabetes	335
- hematoma of, gangrene of fingers from	322
- herpes zoster of (Fig. 110) 124, (Fig. 685) 491	
- hyperæsthesia in, after herpes zoster	546
- hyperidrosis of, in brachial neuralgia	543
- intention tremor in	883
- intermittent claudication in	204
- jerk, lost	615
- (and see Biceps Jerk; Triceps Jerk, etc.)	
- lymphatic drainage of muscles (see Muscles of Arm)	816
- myoma cutis on	889
- myopathy affecting	625
- nerve-supply of	543
- œdema of (see Œdema)	
- pain in (see Pain)	
- paræsthesia in, from cervical pachymeningitis	142
- rib	674
- in tabes dorsalis	545

Arm, contd.

- PARALYSIS OF** .. 611
 - (and see Paralysis of Arm)
 - in phocomelus .. 234
 - pigmented, in pellagra (Fig. 224) .. 280
 - poliomyelitis affecting sensory centre for .. 620

 - nervous subjects .. 664
Arsenic, Addison's disease simulated by .. 83
 - albuminuria from .. 16
 - amblyopia due to .. 922
 - anaemia from .. 44
 - angioneurotic oedema simulated after .. 514
 - anosmia due to .. 756
 - in atoxyl .. 277
 - beer .. 85, 642, 645
 - bleeding gums from .. 93, 94
 - blood per anum from .. 96, 102, 103
 - in blood diseases .. 83, 872
 - brachial neuritis from .. 544
 - burning pain in epigastrium from .. 338
 - cacogeusia due to .. 860
 - choleraic diarrhoea from .. 872
 - in chorea .. 85, 103, 623, 872
 - clammy cold sweats from .. 103
 - colic from .. 83, 148, 525
 - collapse from .. 103, 872
 - contracture due to .. 177
 - coryza due to .. 223, 224, 756
 - depression from .. 338
 - dermatitis due to .. 917

Arsenic, contd.

- in diagnosing syphilis .. 684
 - diarrhoea from .. 83, 94, 103, 216, 217, 338
 - epigastric pain from .. 103
 - epiphora from .. 273
 - erythema from .. 275
 - faintness from .. 338
 - fatty heart from .. 70
 - in food .. 873
 - galy .. 277
 - gangrene from .. 320
 - gastric mucosa inflamed by .. 338
 - ulcer simulated by .. 103
 - gastritis simulated by .. 929
 - general oedema from .. 514
 - hamatemesis from .. 336
 - in hair .. 45, 94, 103, 645, 873
 - hair analysis for .. 85
 - headache from .. 83
 - herpetiform eruptions from .. 83
 - hyperaesthesia due to .. 83, 94
 - hyperkeratosis from .. 45
 - hysterical girls giving .. 873
 - intestinal catarrh from .. 217
 - in kharsivan .. 277
 - leucopenia from .. 455
 - in lymphadenoma .. 643
 - (Fig. 505) .. 643
 - Marsh's test and .. 103
 - mucus in stools from .. 103
 - murder by .. 85, 94, 103
 - nausea from .. 83, 338
 - in neosalvarsan .. 277
 - neuritis from .. 45, 80, 83, 85, 94, 177, 520, 541, 570, 571, 616, 623
 - noises in head from .. 504
 - pains in limbs from .. 83
 - in pernicious anaemia .. 44, 85, 103, 641, 872
 - photophobia from .. 639, 640
 - pigmentation of mouth from .. 642
 - skin from .. 44, 83, 94, 467, 642, (Fig. 505) .. 643
 - poisoning, acute, symptoms of .. 338
 - chronic, symptoms of .. 83
 - epidemic .. 85
 - general account of .. 44
 - Manchester epidemic .. 85
 - obscure cases of .. 873
 - polythaemia from .. 650
 - pyralism from .. 661
 - pulse irregular from .. 103
 - purpura due to .. 676
 - Reimsch's test and .. 103
 - rice-water stools from .. 338
 - in salvarsan .. 277
 - and its allies .. 422
 - severe diarrhoea from .. 650
 - in skin diseases .. 103
 - sodium cacodylate .. 277
 - stools .. 103
 - suicide by .. 872
 - talipes from .. 177
 - tenderness in epigastrium from .. 103
 - tenesmus from .. 872, 873
 - ulcerative colitis simulated by .. 103
 - used by shell workers .. 917
 - vertigo from .. 504
 - in vomit .. 103, 338
 - vomiting due to .. 83, 94, 103, 338, 872, 929
 - in water .. 873
 - weed-killer .. 85, 94, 103, 873
 - willful administration .. 873
Arsenoid, calcium in ferrosilicon .. 421
Arseniuretted hydrogen, fainting due to .. 297
 - from ferrosilicon .. 421
 - haemoglobinuria from .. 357
 - jaundice due to .. 408
 - poisoning in balloon fillers .. 421
 - jaundice in .. 421
Arsenobenzol compounds, jaundice due to .. 408
 - toxic effects of .. 422
Arsenobillon, toxic effects .. 422
Arterial tension (see Blood-pressure)

- Arteriosclerosis**, accentuated aortic second sound in .. 2, 14
 - first sound in .. 14
 - age incidence of .. 204
 - albuminuria due to .. 9, 16, 390, 504, 655
 - albuminuric retinitis with .. 371
 - angina pectoris from .. 654, 864
 - ascites from .. 14, 62
 - and atheroma, sphygmomanometer in distinguishing .. 1
 - blindness in .. 925
 - cerebral haemorrhage with .. 184, 382
 - tumour simulated by .. 371
 - Cheyne-Stokes breathing from .. 139
 - dead fingers from .. 204
 - diabetes and .. 318, 322
 - difficulty in concentration from .. 14
 - dyspnoea from .. 246
 - epistaxis from .. 273, 275
 - fainting due to .. 298
 - gangrene from .. 318, 322
 - general account of .. 14
 - kiddiness from .. 14
 - gout and .. 322
 - granular kidney and .. 264
 - haematemesis from .. 342
 - haematuria from .. 348
 - haemoptysis from .. 362
 - headache in .. 370, 371, 372
 - heart enlarged from .. 14, 71, 264
 - failure from .. 14, 62, 201, 246, 264, 268
 - impulse displaced in .. 373
 - heart-block in .. 109
 - high blood-pressure in .. 1, 14, 17, 62, 71, 105, 106, 201, 204, 246, 372, 390, 504, 729
 - hyperaemia in .. 920
 - hypertrophy of left ventricle with .. 2, 258, 729
 - apothemia in .. 392
 - insomnia from .. 402, 404
 - intermittent claudication with .. 204, 542
 - juvenile .. 237
 - kidney changes in .. 14
 - menorrhagia from .. 482, 484
 - metrorrhagia from .. 487
 - mitral regurgitation from .. 262, 264, 373
 - noises in head from .. 504
 - nutmeg liver from .. 14, 463
 - oedema of legs in .. 14
 - in old age .. 322
 - optic neuritis with .. 371
 - orthopnea in .. 14
 - pain in spine from .. 871
 - palpitation from .. 594
 - pancreatitis from .. 128
 - from polycystic disease .. 57, 450
 - polyuria due to .. 654, 655
 - precordial pain in .. 14
 - in progeria .. 237
 - prolonged first sound with .. 2
 - ptyalorrhoea and .. 662
 - pulmonary congestion in .. 14
 - pulse-pressure in .. 105
 - reduplicated first sound with .. 729
 - relation to granular kidney .. 14
 - renal tube-casts with .. 15, 655
 - shortness of breath in .. 14
 - singing in ears from .. 14
 - spasm of retinal artery in .. 725
 - in Stokes-Adams' disease .. 183
 - tenderness of spine from .. 871
 - throbbings in head from .. 371
 - tinnitus due to .. 878, 879
 - vertigo due to .. 504, 911
 - vomiting from .. 371
Arteriovenous aneurysm (see Aneurysm)
Artery, axillary, aneurysm of (see Aneurysm)

Artery, axillary, contd.

- secondary growth round .. 322
 - brachial, atheroma of, unequal pulses from .. 674
 - carotid, arteriovenous aneurysm of .. 847
 - atheroma of, tinnitus due to .. 878
 - cavernous sinus opened by .. 285
 - cerebral, atheroma of, noises in head from .. 504
 - vertigo from .. 504
 - comes nervi mediani, celiac axis, aneurysm of .. 413
 - enlarged .. 673
 - coronary, atheroma of (see Atheroma)
 - disease of, death in sleep from .. 115
 - dyspnoea from .. 247
 - electrocardiogram normal with .. 115
 - heart normal size with .. 115
 - pain in shoulder from .. 580
 - shortness of breath from .. 114, 115
 - sudden death from .. 115
 - obstruction of, fibroid heart from .. 264
 - from syphilis .. 264
 - spasm of .. 54
 - thrombosis of (see Thrombosis)
 - cut, fainting from .. 297
 - dorsalis pedis, cessation of pulse in .. 46
 - embolism of, in infective endocarditis .. 46
 - external iliac, aneurysm of .. 827, 832
 - femoral, ligature of, gangrene from .. 322
 - for popliteal aneurysm .. 322
 - hepatic, aneurysm of (see Aneurysm)
 - hyaloid, persistent, amblyopia with .. 922
 - nystagmus due to .. 922
 - iliac, aneurysm of (see Aneurysm)
 - intercostal, supplying pulmonary .. 143
 - ligature of, gangrene from .. 322
 - mesenteric, embolism of (see Embolism)
 - middle cerebral, aphasia and .. 771
 - embolism of (see Embolism)
 - endarteritis of, hemiplegia from .. 381
 - obliterans of .. 630
 - syphilis of .. 630
 - hemiplegia from .. 381
 - thrombosis of, hemiplegia from .. 381
 - ophthalmic, arteriovenous aneurysm of .. 847
 - pancreatic, opened by gastric ulcer .. 339
 - popliteal, aneurysm of (see Aneurysm)
 - atheroma of, gangrene from .. 540
 - Morton's neuralgia from .. 540
 - posterior cerebral, lesion of, hemianopsia from .. 379
 - inferior cerebellar, thrombosis of (see Thrombosis)
 - tibial, cessation of pulse in .. 46
 - embolism of, in infective endocarditis .. 46
 - pulmonary, aneurysm of, haemoptysis from .. 362
 - arising from aorta .. 196
 - atheroma of (see Atheroma)
 - congenital hypoplasia of .. 120

Artery, pulmonary, contd.
 -- embolism of, faint-
 ing due to .. 297
 -- supplied by inter-
 costal .. 143
 -- thrombosis of, in
 mitral stenosis .. 363
 -- radial, cessation of
 pulse in .. 46
 -- embolism of, in infec-
 tive endocarditis .. 46, 674
 -- thickened, in Bright's
 disease .. 263
 -- retinal, constricted by
 quinine .. 922
 -- embolism of (see Em-
 bolism)
 -- spasm of, in arterio-
 sclerosis .. 925
 -- blindness due to .. 925
 -- due to quinine .. 925
 -- thin, in high blood-
 pressure .. 106
 -- tortuous, in high
 blood-pressure .. 106
 -- spasm of, ulcer of foot
 from .. 893
 -- spinal, thrombosis of
 (see Thrombosis)
 -- splenic, opened by
 gastric ulcer .. 339
 -- subclavian, abnormal,
 dysphagia from .. 241
 -- morbus coeruleus
 with .. 241
 -- transposition of
 viscera with .. 241
 -- aneurysm of (see
 Aneurysm)
 -- atheroma of, unequal
 pulses from .. 674
 -- cervical rib kinking
 first rib compressing,
 pulsus paradoxus
 from .. 664
 -- systolic bruit
 due to .. 664
 -- unduly pulsatile .. 864
Arthritis, acute, of infants
 -- secondary .. 425
 -- albuminuria with .. 21
 -- of ankle, dorsiflexion
 during treatment of .. 147
 -- septic, talipes from .. 147
 -- in congenital syphilis
 .. 291, 432
 -- crackling in .. 188
 -- from diphteria .. 425
 -- dysentery .. 425
 -- epitrochlear gland en-
 larged from .. 476
 -- from glanders .. 425
 -- gonococcal, account of
 .. 425
 -- ankylosis from .. 425
 -- deformity from .. 425
 -- fingers affected by .. 425
 -- flat-foot from .. 425
 -- heel .. 425
 -- hand affected by .. 425
 -- knee affected by .. 425
 -- muscular atrophy
 from .. 425
 -- nodules with .. 423
 -- with ophthalmia .. 425
 -- pain in foot from .. 425
 -- limbs from .. 568
 -- sole with .. 429
 -- plantar fascia affected
 by .. 425
 -- progressive muscular
 atrophy simulated by .. 425
 -- rheumatic fever simu-
 lated by .. 425
 -- (Fig. 329) 423, 425
 -- salicylates not affecting
 (Fig. 329) 423, 425
 -- suppuration rare in .. 425
 -- temperature chart in
 (Fig. 329) 423
 -- tendons affected by .. 425
 -- tuberculous joint
 simulated by .. 429
 -- with urethral dis-
 charge .. 425
 -- wrist affected by .. 425
 -- years after gonorrhoea .. 552
 -- gouty (see Gout)
 -- in hemophilia .. 435

Arthritis, contd.
 -- infective, anaemia from .. 43
 -- from dental sepsis .. 95
 -- fibrositis and .. 566
 -- myositis and .. 566
 -- of spine .. 796
 -- abdominal pain .. 151
 -- from .. 151
 -- colic simulated by .. 151
 -- pain in iliac fossa
 from .. 555, 558
 -- between shoul-
 ders from .. 566
 -- from influenza .. 425
 -- injury .. 581
 -- in Malta fever .. 425, 571
 -- from measles .. 425
 -- meningococcal menin-
 gitis .. 425
 -- occupation neurosis sim-
 ulating .. 581
 -- osteo- (see Osteo-arthritis)
 -- from osteomyelitis .. 425
 -- paralysis simulated by .. 424
 -- pneumococcal .. 424
 -- in children .. 424
 -- elbow affected by .. 424
 -- incision and drainage
 for .. 424
 -- injury and .. 424
 -- knee affected by .. 424
 -- needling of joint in .. 424
 -- from otitis media .. 424
 -- pneumonia .. 424
 -- septicæmia from .. 424
 -- shoulder affected by .. 424
 -- yellow-green pus in .. 424
 -- popliteal glands en-
 larged from .. 477
 -- due to rheumatic fever .. 423
 -- rheumatoid .. 47, 426
 -- acute (Fig. 332) 426
 -- anaemia in .. 47
 -- ankylosis from .. 179
 -- Bacillus coli com-
 muns causing .. 47
 -- dysentery causing .. 47
 -- bacteriological classi-
 fication of .. 47
 -- bone rarefaction in .. 431
 -- without bony deformity
 (Fig. 335) 427, 431
 -- cachexia with .. 128
 -- in childhood .. 128
 -- (Fig. 381) 472, 781
 -- constitutional sym-
 ptoms with .. 47
